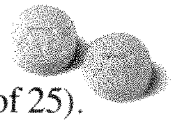
WELLCOVORIN® TABLETS

(leucovorin calcium)

The First Leucovorin Rescue With Oral Convenience

As a result of advanced technology,
Wellcovorin is the first leucovorin calcium available in convenient tablet form.
With Wellcovorin Tablets, no reconstitution of vials, mixing of special solutions,
or cumbersome breaking of ampuls is necessary.



For greater flexibility in oral dosing, Wellcovorin Tablets come in two sizes: 5 mg (scored, bottles of 100) and 25 mg (scored, bottles of 25).

Consider Enhanced Quality of Life:

Often discharged from the hospital earlier, many patients can complete their course of therapy on an outpatient basis and return to a more normal, comfortable lifestyle sooner.

Consider Less Costly Care:

Mg for mg, Wellcovorin Tablets are less expensive than injectable leucovorin. Plus, with Wellcovorin Tablets, hospital stays are often shorter and clinic visits less frequent.

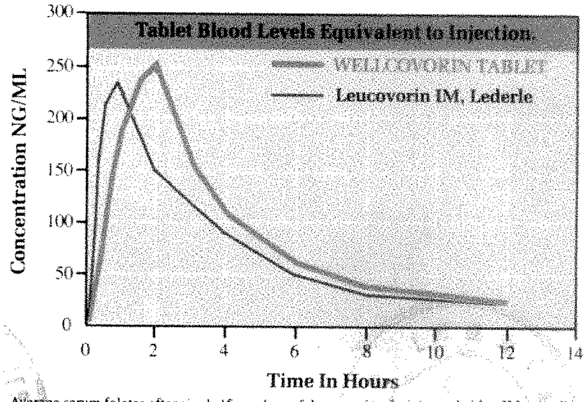
Consider Greater Patient Comfort:

Patients no longer need to drink special liquid formulations or endure a series of painful needle punctures. Patients simply take the prescribed number of Wellcovorin Tablets with water.

Consider Assured Blood Levels:

Wellcovorin Tablets are bioequivalent to equal amounts of injectable leucovorin, whether it is administered intravenously or intramuscularly (peak serum concentrations are reached after approximately two hours).

Blum MR, Guaspari A, Liao SHT, et al. Bioavailability and pharmacokinetics of oral and parenteral leucovorin. 33rd National Meeting Pharm Sci. San Diego, California, 1982, 12(2):175.



Average serum folates after single 15 mg dose of leucovorin administered either IM or orally. Adapted from Blum, et al

Please see brief summary of prescribing information on next page.

WELLCOVORIN® TABLETS
(leucovorin calcium)
Leucovorin in convenient 5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m^2 orally or parenterally followed by 10 mg/m^2 orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m^2 every three hours until the serum methotrexate level is below 5×10^{-8}M.[1,2]

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[3,4,5]

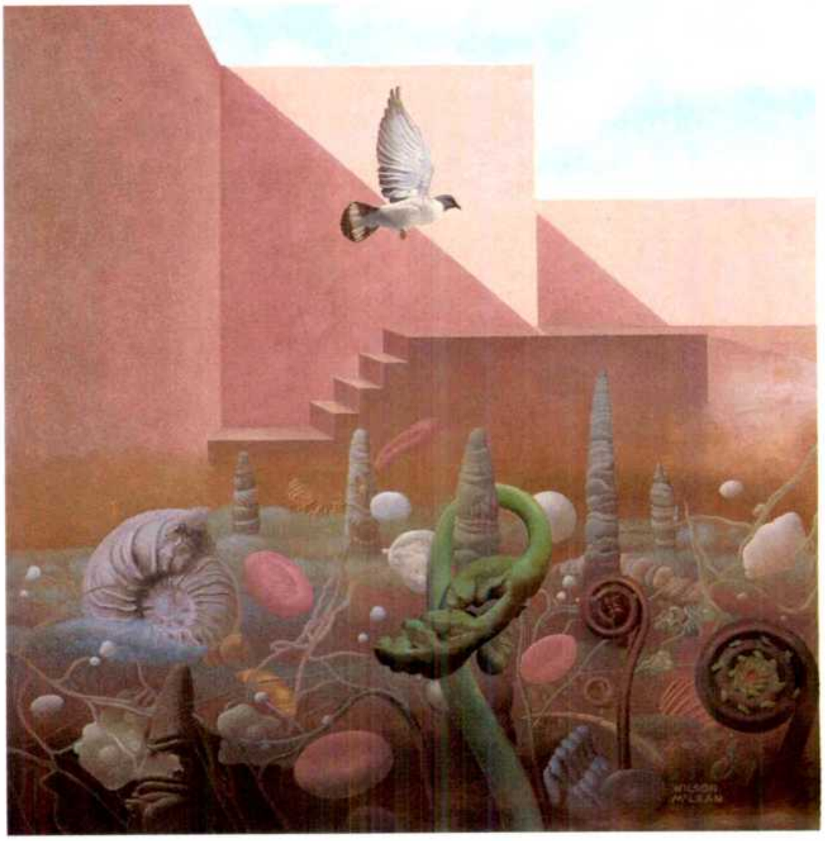
NOW THE WAY IS CLEAR FOR YOU TO PROVIDE LEUKOPOOR PLATELETS

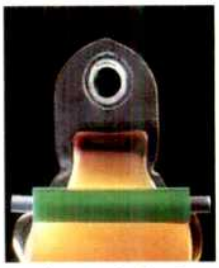


...WITH THE CUTTER LEUKOTRAP™ PLATELET POOLING SYSTEM.

Now, leukopoor platelets can be routinely used for treatment of patients on platelet therapy to reduce or eliminate leukocyte-associated transfusion reactions. Leukotrap is the first commercially available system for *routine* production of leukopoor platelets.

MOST EFFICIENT METHOD

The Leukotrap System removes 90% of leukocytes and residual red cells with only 10% platelet loss.



Leukotrap™ Pooling Bag shown after completed procedure with leukocytes and residual red cells trapped in the pouch.

SIMPLE, FAST PROCEDURE

The Leukotrap System requires minimal technician time and a standard centrifuge.

Provide a better platelet product...with the Leukotrap Platelet Pooling System.

For more information, contact your Cutter Biological Representative or call our Professional Services Department at (800) 227-1762.

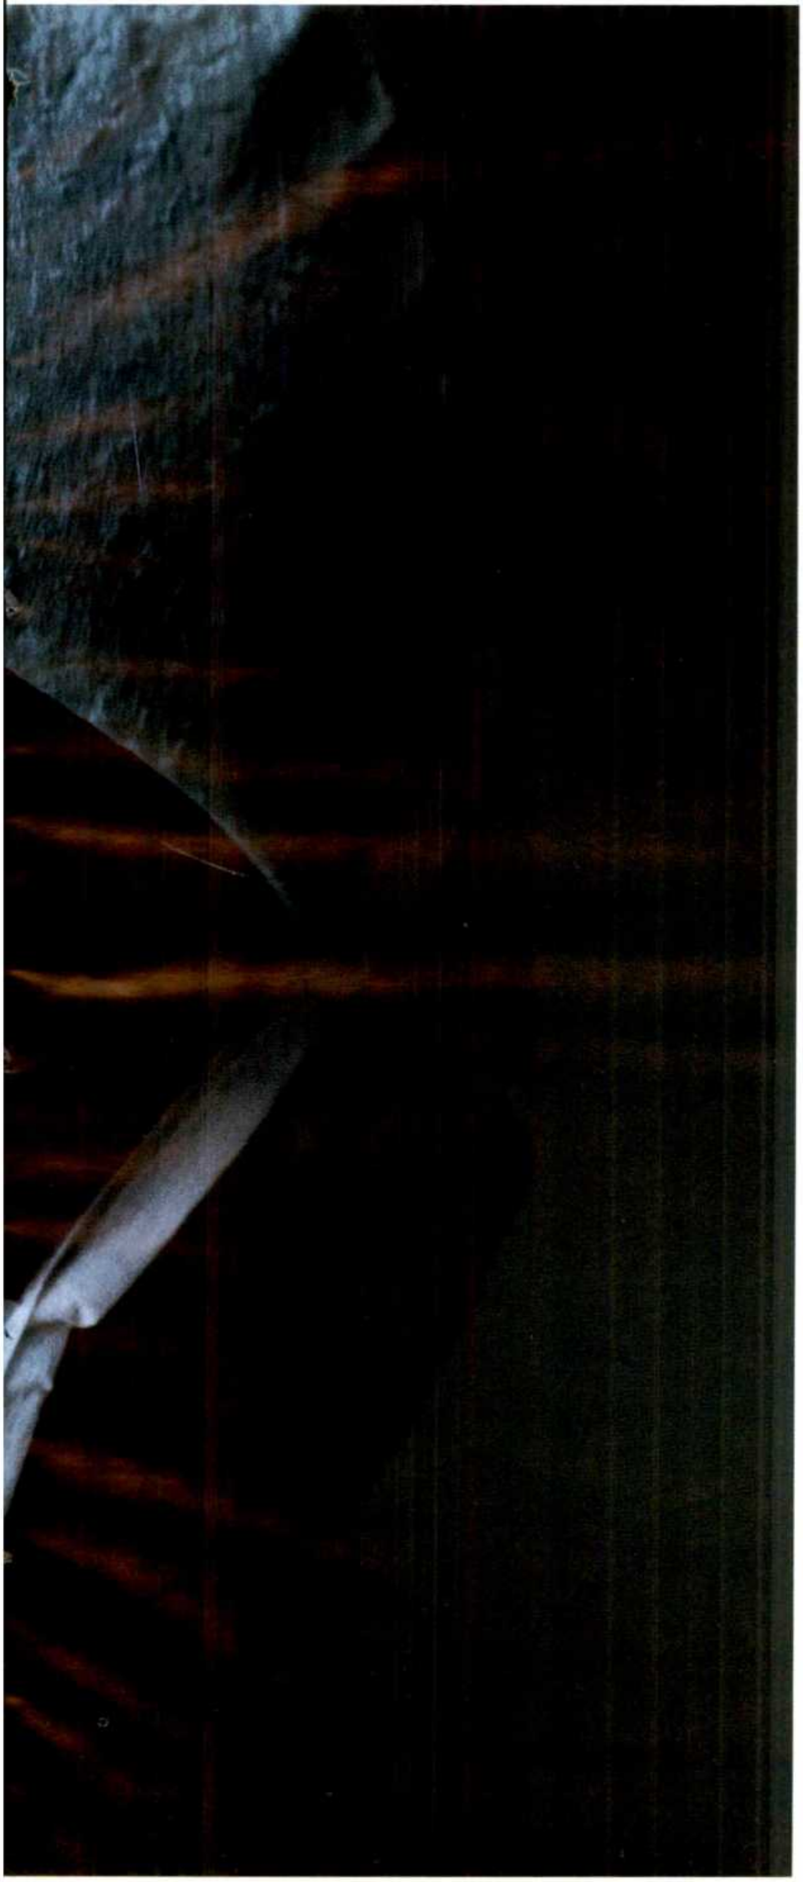
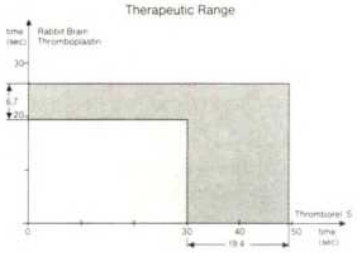
travelling the narrow path between thrombosis and bleeding has become safer!



Good news for all physicians engaged in surgery, laboratory and internal medicine.

With the new Thromborel S from human placenta the prothrombin time (PT) has become more precise and internationally comparable.

Thromborel® S
is the first commercial thromboplastin standardized against the British Comparative Thromboplastin (BCT), the international reference thromboplastin from human brain.



To make monitoring of patients treated with oral anticoagulants safer, we extended the time span between upper and lower limit of the therapeutic range to about 18 (!) seconds.

This should prove a better aid for guidance between the risk of bleeding or thrombosis.

The newest volume in an authoritative series!

PROGRESS IN LIVER DISEASES, VOLUME VIII

Edited by

Hans Popper, M.D., Ph.D. **Fenton Schaffner, M.D., M.S.**

Progress in Liver Diseases, Volume VIII continues in the tradition of providing authoritative reviews of published data on the liver and its diseases.

This volume includes up-to-date coverage of cell pathobiology and molecular biology. Common hepatic diseases, forms of cholestasis, and alcoholic liver injury are also discussed. Types of viral hepatitis, including delta agent disease, are covered in a major section, along with the hepatitis B vaccine and the relation of hepatitis B infection to hepatocellular carcinoma. This comprehensive survey of the current status of liver diseases will benefit specialists and residents in hepatology, gastroenterology, and internal medicine.

TENTATIVE CONTENTS (Partial): *Kamal G. Ishak,* Applications of Scanning Electron Microscopy to the Study of Liver Disease. *Christiane Guguen-Guillouzo, Michel Bourel, and André Guillouzo,* Human Hepatocyte Cultures. *Jeffrey M. Hoeg and H. Bryan Brewer, Jr.,* Human Lipoprotein Metabolism and the Liver. *David Zakim,* The Role of Membrane Lipids in the Regulation of Membrane-Bound Enzymes. *Luigi M. DeLuca and Kim E. Creek,* Vitamin A and the Liver. *Clifford J. Steer and Gilbert Ashwell,* Hepatic Membrane Receptors for Glycoproteins. *Paul D. Berk and Wolfgang Stremmel,* Hepatocellular Uptake of Organic Anions. *Irwin M. Arias,* Mechanisms and Consequences of Ion Transport in the Liver. *Beatriz Tuchweber, Andrée Weber, Claude C. Roy, and Ibrahim M. Yousef,* Mechanisms of Experimentally Induced Intrahepatic Cholestasis. *H.C. Thomas and A.M.L. EPICS® C

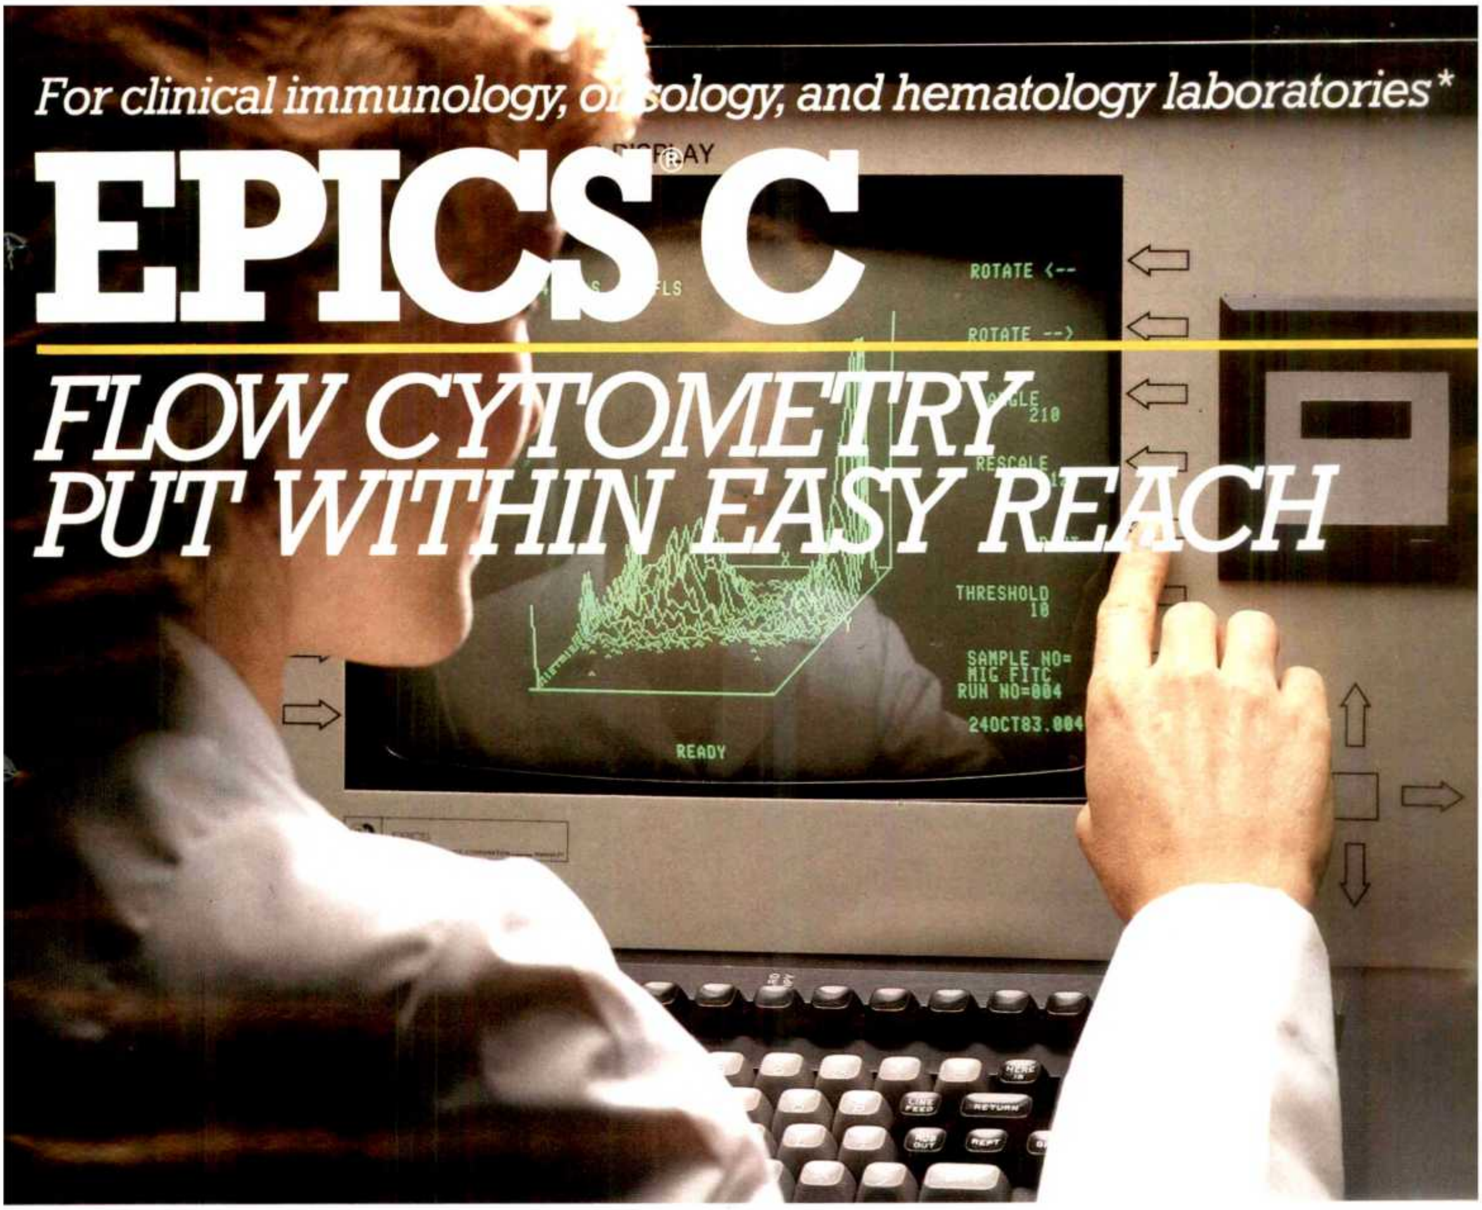
FLOW CYTOMETRY PUT WITHIN EASY REACH



With ease of input

fast sample preparation of dual-color labeling in whole blood is ready in less than one hour

convenient touchpad operation provides automatic control for your protocol configuration and analysis selection, and eliminates lengthy or complex computer interface

easily aligned straight-through optics remain stable, resulting in precise and reproducible measurements

computerized graphics display different cell types and percents of each population with superior resolution, using three-dimensional histograms and contours

automated analysis and sorting processes up to 10,000 cells per second; sorts more than 5,000 cells per second for fast and accurate results

easy-to-modify protocols give you the flexibility of choosing from preprogrammed protocols or redesigning them to meet special needs

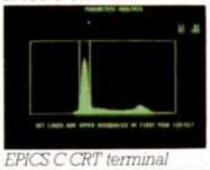
EPICS DIVISION
OF COULTER CORPORATION ——— Hialeah, Fl

Artfully advancing the science of flow cytometry

For depth of insight

The EPICS C flow cytometry system is equipped to provide your clinical lab with new insights into a variety of diseases. The unique *straight-through* optics focus a *high-powered laser* on individual human cells, while a *built-in computer* precisely analyzes the patient sample. Data collected on the EPICS C can be displayed on either the EPICS C or Easy System CRT terminals.

EPICS C CRT terminal



EPICS C CRT terminal

Easy System CRT terminal

In immunology: Many immunological disorders, including leukemia and AIDS, have telltale leukocyte abnormalities. The EPICS C analyzes white blood cells and displays graphs of their subpopulations (lymphocytes, monocytes, and granulocytes) for additional information on these diseases.

In oncology: Through the use of PARA 1 software on the EPICS C, the relative number of cells in each phase of the cell cycle can be determined. Aneuploid populations, tumor cells that contain an abnormal amount of DNA, can appear as separate peaks on a DNA histogram and can be quantitated.

In hematology: The EPICS C provides reliable and automated reticulocyte enumeration. In only two minutes, the EPICS C can automatically count 100,000 total cells, minimizing sampling error of tedious manual procedures.

For information on EPICS® C flow cytometry, complete and mail coupon to: EPICS DIVISION of Coulter Corporation, P.O. Box 4486, Hialeah, FL 33014 or call: 1-800-ME-EPICS

HERPES SIMPLEX INFECTION IN THE COMPROMISED HOST:

OFTEN SERIOUS, TOO OFTEN UNSUSPECTED

Number one in a series of typical case presentations.

Esophagitis in a leukemia patient

In patients with hematologic malignancies, the visceral organ most frequently involved by herpes simplex virus (HSV) infection is the esophagus.[1] Extensive ulcerative lesions may develop on the upper two thirds of the esophagus with confluent lesions of the distal third.[2] In some cases, however, the mucosa may be grossly unremarkable even when microscopic examination shows evidence of herpetic ulcerative esophagitis.[1] Similarly, some patients may display symptoms of dysphagia and burning retrosternal pain,[3] whereas others may appear asymptomatic.[1] The diagnostic method of choice for patients with suspected herpetic esophagitis is esophagoscopy with visualization of the mucosa and procurement of cytologic and biopsy specimens from ulcerated areas.[1]

References: 1. Buss DH, Scharyj M: Herpesvirus infection of the esophagus and other visceral organs in adults. Incidence and clinical significance. *Am J Med* 1979;66:457-462. **2.** Wong KK, Hirsch MS: Herpes virus infections in patients with neoplastic disease. Diagnosis and therapy. *Am J Med* 1984; 76:464-478. **3.** Lightdale CJ, Wolf DJ, Marcucci RA, et al: Herpetic esophagitis in patients with cancer: Ante mortem diagnosis by brush cytology. *Cancer* 1977;39:223-226.

Herpetic infections may result in extensive disease and death

Immunocompromised patients are highly vulnerable to HSV infection. Such infections may interrupt therapy and even lead to death if not detected early and managed aggressively.[1] Although the initial appearance may be mild, HSV infection may progress to severe localized mucocutaneous ulcerations. The greatest threat that herpes simplex poses is an infection that disseminates from a mucocutaneous or unrecognized primary lesion and involves the lungs, liver, esophagus, or central nervous system.[1] Furthermore, herpetic ulcers frequently provide an entry for secondary bacterial and fungal pathogens.[2]

Infections may not be diagnosed correctly without virologic study

Some investigators claim that the actual incidence of serious HSV infection is probably higher than reported because "the possibility of herpetic disease is insufficiently considered and appropriate diagnostic viral studies are often not carried out."[3] One study, for example, found histocytologic evidence of visceral herpes infection in 56 patients even though herpetic involvement was not suspected in any of the patients prior to autopsy.[2]

ZOVIRAX I.V. halts viral replication and speeds healing even in debilitated patients

ZOVIRAX I.V. has been shown to be a highly effective treatment for severe mucocutaneous HSV infection in immunocompromised patients. In controlled trials, ZOVIRAX I.V. rapidly halted viral shedding — within 3 days in most patients — and significantly shortened healing time as well as duration of pain.[4,5] Furthermore, ZOVIRAX I.V. may allow patients to return home sooner and enable patients with intraoral lesions to resume normal eating habits.[6]

ZOVIRAX I.V. is well tolerated by immunocompromised patients

A multicenter collaborative trial of ZOVIRAX I.V. in immunocompromised patients reported that: "Clinical benefits were obtained without appreciable toxicity. The most common reactions were irritation of peripheral veins used for drug infusion and a low incidence of rash.... Significant renal or hematologic toxicity did not occur, even in these seriously ill patients who were commonly receiving other drugs concomitantly."[5]

Note: Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes. Please see brief summary for more information.

An effective response to a life-threatening infection

ZOVIRAX® I.V. INFUSION

(acyclovir sodium) sterile powder

An effective response to a life-threatening infection

ZOVIRAX® I.V. INFUSION

(acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M^2 every 8 hours (750 mg/M^2/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.[1,2,3]

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.[4]

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.[5]

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[6]

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously, or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS and DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M^2) over an hour was associated with a lower frequency — 4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 6 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the I.V. fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonitis, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.8 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitters, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION — RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: ***MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 and HSV-2) INFECTIONS IN IMMUNOCOMPROMISED PATIENTS*** — 5 mg/kg infused at a constant rate over 1 hour, every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M^2 at a constant rate over 1 hour, every 8 hours (750 mg/M^2/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS — The same dose given above — administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M^2)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

Blenoxane® ...*Integral Component of Chemotherapy Regimens in Non-Hodgkin's Lymphoma*

(sterile bleomycin sulfate)

Since Blenoxane is virtually non-myelosuppressive, continuing therapy with certain Blenoxane containing chemotherapy regimens (e.g. BACOP) can prevent tumor regrowth between cycles of other chemotherapy regimens while allowing for bone marrow recovery.[*2,3,4,6]

Blenoxane can produce, with cumulative doses, a syndrome of pulmonary fibrosis. It is usually dose-related, being seen infrequently in patients whose total dose of Blenoxane is less than 400 units.

Blenoxane® *(sterile bleomycin sulfate)*

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane® be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma – Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas – Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma – Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary – This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{co}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{co} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{co} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

(1) Maintain FI O_2 at concentrations approximately that of room air (25%) during surgery and the postoperative period.

(2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions – In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes – These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other – Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban®. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20

PROGRESS IN HEMATOLOGY

Volume XIV

Edited by

Elmer B. Brown, M.D.

A REVIEW FROM THE SILVER ANNIVERSARY ISSUE:

"As the scientific literature expands and the rate of accumulation of new information accelerates, the need for critical synthesis of the literature is more and more strongly felt . . . For more than two decades, ***Progress in Hematology*** *has served the useful purpose in a field that includes hematology in its broadest sense...intended for the hematologist, in research, practice or training, who wants to have an overview of the areas with which he is not dealing directly."*

For Fastest Service CALL TOLL-FREE 1-800-321-5068. To Place An Order From Florida, Hawaii, Or Alaska CALL 1-305-345-4100. In The U.K. CALL (01) 300-0155. Send payment with order and save postage and handling. Prices are in U.S. dollars and are subject to change without notice.

Progress in Hematology, Volume XIV continues in the tradition of previous volumes by providing thorough coverage of the most important clinical and research topics in the field.

Authorities from the United States and abroad review their areas of special expertise to provide the guidance needed to both stay abreast of the rapid changes in hematology and to educate students about its tools and concepts.

This informational synthesis will appeal to medical students, residents, fellows, clinical and laboratory physicians interested in hematology, medical teachers and investigators, and all medical libraries. Through careful reading, the volume offers the ability to identify, evaluate, and place in perspective these signifcant contributions to the literature of hematology.

For safety's sake...

LEUCOVORIN
Calcium Injection

Whenever a folic acid antagonist is administered, Leucovorin Calcium should be readily available to help offset possible toxicity.

Leucovorin Calcium from Lederle Laboratories is considered to be highly effective in counteracting the life-threatening effects of possible overdosage of a folic acid antagonist.

And for the sake of convenience,

Leucovorin Calcium is available in two different forms:

Ampuls of 3 mg, preservative-protected liquid.

Vials of 50 mg cryodesiccated powder for multiple dose use. Remains stable for 7 days after reconstitution with diluent containing benzyl alcohol.

For more information, contact your Lederle Representative or call the Lederle Professional Medical Services Department at (914) 735-5000.

LEUCOVORIN CALCIUM INJECTION

DESCRIPTION Each 1 ml ampul of Leucovorin Calcium *Lederle* contains Leucovorin 3 mg as the calcium salt which is the form preferred for intramuscular injection. Preservative: benzyl alcohol 0.9% w/v. The inactive ingredients are sodium chloride 0.56% w/v, Water for Injection qs 100% and sodium hydroxide or hydrochloric acid is used to adjust the pH to approximately 7.7.

Each 50mg vial of Leucovorin Calcium cryodesiccated powder when reconstituted with 5 ml of sterile diluent contains Leucovorin 10 mg per ml as the calcium salt which is the form preferred for intramuscular injection. Contains no preservative. Dilute only with Bacteriostatic Water for injection USP which contains benzyl alcohol. The inactive ingredients are sodium chloride 40mg/vial, and sodium hydroxide or hydrochloric acid qs to pH approximately 8.1. When reconstituted as directed, the resulting solution must be used within 7 days. If the product is reconstituted with Water for Injection USP, use immediately.

ACTIONS Leucovorin (folinic acid) is the formyl derivative and active form of folic acid. Leucovorin Calcium is useful clinically in circumventing the action of folate reductase. There is no evidence that intramuscular doses of greater than 1 mg have greater efficacy than those of 1 mg.

INDICATIONS Indicated (a) to diminish the toxicity and counteract the effect of inadvertently administered overdosages of folic acid antagonists. (See Warnings). (b) In the treatment of the megaloblastic anemias due to sprue, nutritional deficiency, pregnancy, and infancy when oral therapy is not feasible.

CONTRAINDICATIONS Not to be administered for the treatment of pernicious anemia or other megaloblastic anemias where Vitamin B_{12} is deficient.

WARNINGS Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

In the treatment of overdosage of folic acid antagonists, Leucovorin must be administered within 1 hour, if possible, and is usually ineffective if administered after a delay of 4 hours.

PRECAUTIONS In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive.

ADVERSE REACTIONS Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

DOSAGE Megaloblastic anemia: No more than or up to 1 mg daily. There is no evidence that intramuscular doses greater than 1 mg daily have greater efficacy than those of 1 mg; additionally, loss of folate in the urine becomes roughly logarithmic as the amount administered exceeds 1 mg.

For the treatment of overdosage of folic acid antagonists: To be given in amounts equal to the weight of the antagonist given.

HOW SUPPLIED 6-1 ml Ampuls—Product Number 4004
50 mg Vial of Cryodesiccated powder—Product Number 5330

REVIEW

Lineage Promiscuity in Hemopoietic Differentiation and Leukemia

By M.F. Greaves, L.C. Chan, A.J.W. Furley, S.M. Watt, and H.V. Molgaard

An increasing number of reports document instances in which individual leukemic cells coexpress markers normally believed to be restricted to a single lineage. This has been interpreted by McCulloch and colleagues as aberrant programming or lineage infidelity and contrasts with earlier suggestions that lineage fidelity of gene expression was usually maintained in leukemia. We argue that several examples of infidelity are suspect on technical grounds, whereas others are bona fide and require explanation, eg, partial rearrangements and expression of Ig heavy-chain and/or T cell receptor genes in inappropriate cells and terminal deoxynucleotidyl transferase in leukemic myeloblasts. Individual examples of truly aberrant gene expression may well occur in leukemia but with insufficient regularity to be of general significance. We suggest that verifiable and consistent examples of apparent lineage infidelity do not reflect genetic misprogramming but rather the existence of a transient phase of limited promiscuity of gene expression occurring in normal bipotential or multipotential progenitors and able to be preserved as a relic in leukemic blast cell populations that are in maturation arrest. This alternative explanation has interesting implications for mechanisms of hematopoietic differentiation and leads to some testable predictions.

© 1986 by Grune & Stratton, Inc.

IMMUNOLOGIC, enzymatic, and molecular investigations of human leukemias and lymphomas support the notion of a unicellular (monoclonal) origin and an apparent maturation arrest or uncoupling of proliferation and differentiation.[1-3] From a consideration of the composite phenotypes of leukemia cells in comparison with normal populations it has been possible, in the majority of cases, to designate the predominant lineage and cell type involved and at least to speculate as to the possible target cell for clonal expansion.[4-6] Such analyses form the basis of new classification schemes and diagnostic programs and have prognostic relevance in the context of particular therapeutic regimes.[7-10]

Leukemic phenotypes are not perfect replicas of normal ones. In addition to specific chromosomal changes and alteration in the structure and/or control of particular genes, leukemic cells may show some asynchrony of phenotypic expression in comparison to their equivalent maturation compartment in normal tissue. In a study of the composite immunophenotype in 82 cases of T cell leukemia, 26 showed some asynchrony or abnormal combination of T cell markers with respect to intralineage maturation status.[11] Additionally, all cases of thymic or T acute lymphoblastic leukemia tested expressed high-density HLA (A, B) combined with nuclear terminal deoxynucleotidyl transferase (TdT) in individual cells,[11,12] whereas in the normal thymus, TdT-positive cells have very low density HLA (A, B), the density of this glycoprotein increasing with further T cell maturation and loss of TdT activity.[13] Similarly, in leukemia of B cell precursors, ie, common acute lymphoblastic leukemia, a substantial proportion of cases are cytoplasmic μ chain positive/TdT-positive,[14,15] whereas in normal populations, this is an extremely rare (though detectable) cellular phenotype,[16] pre–B cells presumably losing TdT prior to detectable μ chain synthesis. Significantly, these distortions in phenotype were much more pronounced in cell lines established from acute lymphocytic leukemia (ALL) patients (usually in relapse) compared with uncultured cells studied at diagnosis.[11]

The minimal deviation or asynchrony of maturation-linked phenotype usually observed in leukemic cells at diagnosis is not surprising if the arrest is not an absolute bar to maturation but, as proposed, a regulatory uncoupling of variable stringency.[17] Lineage specificity, on the other hand, has appeared to be rather faithfully conserved in leukemia and lymphoma. For example, the gp100/common acute lymphoblastic leukemia antigen (CALLA, CD-10) structure[17,18] is non–lineage specific[19] but is selectively expressed on certain cell types in concert with maturation status. Although granulocytes may express CALLA weakly,[20] myeloid progenitors are unreactive[21] in contrast to putative

lymphoid precursors in bone marrow and thymus that are CALLA-positive.[16,22,23] In a survey of over 2,000 cases of leukemia with the anti-CALLA monoclonal J-5,[23] 802 out of 1,072 (74.8%) ALL were reactive compared with only 14 out of 573 (2.4%) cases of acute myelogenous leukemia (AML). More significantly on review of the latter 14 cases, three cases had dual lymphoid-myeloid populations, ten had no unequivocal evidence for myeloid cytochemistry, and one was originally an AML but relapsed as ALL. Nine of these pseudomyeloid leukemias were treated with therapy for ALL, and eight responded well.[23] Clearly, therefore, it is exceedingly rare for leukemic myeloblasts to express illegitimately the CALLA marker. Glycophorin is an erythroid cell–specific membrane glycoprotein expressed on most but not all erythroleukemias.[24] When a monoclonal antibody, LICR.LON.R10,[25] was used to screen 329 cases of ALL, only two had positive blasts.[24] Review of these cases revealed that although both had a lymphoblast morphology, they did not express an ALL immunophenotype and were almost certainly cryptic erythroleukemias.

On the basis of these considerations it was suggested that lineage fidelity was the norm in leukemia and that the stabilization of a normally transient progenitor or precursor cell phenotype was a critical event in leukemogenesis.[3,26,27]

LINEAGE INFIDELITY IN LEUKEMIA: IDENTITY CRISIS FOR CELLS, MONOCLONAL ANTIBODIES, OR INVESTIGATORS?

The idea that leukemic cells are phenotypically similar to normal hematopoietic progenitors or subsets has now been challenged with an increasing number of reports, in particular from McCulloch and colleagues, claiming to have demonstrated lineage infidelity of gene expression (Table 1). Infidelity is defined here according to McCulloch's arguments[59] as a misprogramming of differentiation in leukemia with the consequence that there is coexpression on individual cells of markers normally found only on cells belonging to different but related lineages, eg, lymphoid plus myeloid or granulocytic plus erythroid. McCulloch refers to the former as interlineage infidelity and the latter as intralineage (myeloid) infidelity.[59] Since the term intralineage infidelity might be confused with asynchronous maturation in leukemia (see above), we do not use it here and adhere to the simple definition of interlineage infidelity given previously. This situation should be distinguished from cases of leukemia (often termed biclonal) in which cells of two lineages (eg, myeloid and lymphoid) coexist simultaneously or appear sequentially in an individual patient and presumably reflect the transformation of a common precursor whose progeny have undergone further differentiation.

Table 1. Summary of Reported Examples of Apparent Lineage Infidelity in Leukemia

1	20 acute leukemias studied	
	A 6 cases: factor 8 or spectrin + My-1 or OKM1 binding	
	B Ig + My-1 binding	28
2.	MOLT-3, T-ALL cell line + 5-azacytidine → binding of My-1 and 80H.5 (CDw 15, anti-X hapten) and other antibodies assumed to be unreactive with T cell leukemia—J-5 (and CALLA) and BA-2 (anti-p24).*	29
3.	K562 cell line spectrin + My-1 binding	30
4	Monocytoid cytochemistry in TdT$^+$ lymphoblasts carrying the (4,11) translocation	31
5.	Reactivity with IG10 (anti-X hapten) plus inducible monocytoid features in acute leukemic cell line with the (4,11) translocation and the composite phenotype of a B cell precursor ALL.	32
6	T cell antigen gp65-67kd/T1 (CD-5) expressed in B chronic lymphocytic leukemia (B-CLL).	33
7.	Coexpression of the E rosette receptor, gp50/T11 (CD-2) with monoclonal Ig in lymphoid leukemia.	34–36
8.	Coexpression of T11 with the myeloid marker MY9.	37
9.	Expression of T11 structure (gp50) on leukemic myeloblasts (4/23 AML patients)	38
10	Expression of the granulocytic antigen anti-X hapten antibodies (VIM-D5, LeuM1) on ALL cells	39
11	Coexpression of several T cell antigens (T3, T4, T6, T8, T11) with membrane Ig.	40, 41
12	Expression of myeloid enzymes or myeloid antigen (CDw 13, antibody MCS-2) on ALL cells (three cases) †	42
13.	Expression of T cell antigen gp40/CD-7 (antibodies 3A1, WT1) on leukemic myeloblasts	44–46
14.	Coexpression of T cell and myeloid markers CD-1/VIM-D5 (anti-X hapten), CD-3/VIM-D5, TdT/VIM-D5.	47
15.	Presence of nuclear TdT in leukemic myeloblasts	47–51
16.	Ig gene rearrangement in T leukemic cells or cell lines.	52–54
17	Ig gene rearrangement in myeloid leukemia or myeloid cell line (ML-1).	55–57
18	T cell receptor rearrangement in non-T leukemic cells.	58

*An assumption here that gp100/CALLA and p24/BA-2 are not expressed by T cells and thymic leukemias is clearly false (see refs 11, 23)

†In two of these three cases the presence of myeloid markers in lymphoblasts was not clearly demonstrated.[43]

We regard this issue as being of considerable interest since if infidelity were relatively common it would largely nullify the views summarized previously and might carry important implications for both leukemogenesis and normal differentiation as well as for clinical applications of phenotypic markers. In this article we analyze the evidence presented in support of this concept and propose an alternative interpretation of the data.

It must first be acknowledged that, if leukemic cells very occasionally express an unexpected or ectopic product that is discordant with the overall, composite phenotype, then this should cause no great surprise, especially if it occurs in concert with malignant progression and multiple chromosomal alterations or following prolonged culture in vitro. On the other hand, it is rather unlikely that such an infrequent abnormality can shed any light on fundamental and common mechanisms of leukemogenesis and differentiation. Consistent phenotypic features, at least within a subtype of leukemia, are therefore of more interest. Although some of the reported claims for lineage infidelity in leukemia are anecdotal and have not been substantiated, others demand more attention. Our view is that many of the reported examples of illegitimate gene expression are suspect since they rely upon presumptions of lineage specificity of the marker used that are either unsubstantiated or clearly false. This is most evident with certain monoclonal antibodies in the CDw 15 set[61] that have been used to detect inappropriate expression of granulocyte-associated antigens[28,29,32,38,40,47] (Table 1). Although the original reports of these reagents clearly demonstrated the preferential reactivity of relatively mature myeloid cells with antibodies such as My-1,[62] VEP8/9,[63] MI/N1,[64] VIM-D5,[65] 80.H5,[66] HL-C5,[67] and IG10[68] (Fig 1), it is known that these all detect the same carbohydrate antigen (3-fucosyl-N-acetyllactosamine or X hapten)[69,70] that far from being lineage specific is cross-reactive or identical to the SSEA-1 antigen of teratocarcinomas and certain embryonic cells and expressed in a wide variety of tissues (normal and malignant) and secretions[70] (Fig 1). Within the human hematopoietic system, the X hapten determinant has been identified using some of the aforementioned antibodies on multipotential progenitors and committed progenitors of several lineages[71] and is present in a cryptic but easily exposable form on acute lymphoblastic leukemia cells.[72] Clearly, the presence or exposure of such an antigen on nongranulocytic cells cannot be regarded as evidence for lineage infidelity of gene expression.

Other markers used in reports of infidelity (Table 1) are also suspect. Polyclonal antibodies to spectrin are very unlikely to be erythroid cell specific as assumed[28,30] since spectrin is known to be expressed in a wide variety of cell types including lymphocytes.[73] Neither are several of the T cell differentiation markers restricted to cells of the T lineage as also assumed. This is especially true of Leu-1/OKT1 (CD-5), which was unexpectedly found on B-CLL cells[33] but later identified on an infrequent subset of normal B cells.[74] The situation with other T cell–associated determinants is less clear although T4 (CD-4) is expressed by macrophages[75] and T6 (CD-1) by Langerhans cells in the skin.[76] Several authors report that the T11 (CD-2), E rosette marker of T cells can be expressed by monoclonal (κ or λ) B cell leukemias or leukemic myeloblasts (see Table 1). Expression of the T11 marker on normal, activated B cells has been reported,[36] but its presence on normal myeloid cells has yet to be demonstrated.

Other observations that might reflect infidelity cannot easily be refuted on the basis of reagent specificity or exclusive use of cell lines. These include (see Table 1) the presence of nuclear TdT in leukemic myeloblasts, the presence of gp40/CD-7 T cell–associated proteins on leukemic myeloblasts and, perhaps most strikingly, the rearrangement and/or expression of an immunoglobulin or T cell receptor *β* gene in inappropriate lymphoid or myeloid leukemic cells. We regard these observations as particularly instructive and will discuss them in more detail.

Several other combinations of markers reported to be expressed on individual cells appear to be abnormal. These are, however, mostly on selected, long-established cell lines, in some cases treated with phorbol ester (see Table 1), and the general significance of such observations for gene expression in leukemia is difficult to ascertain.

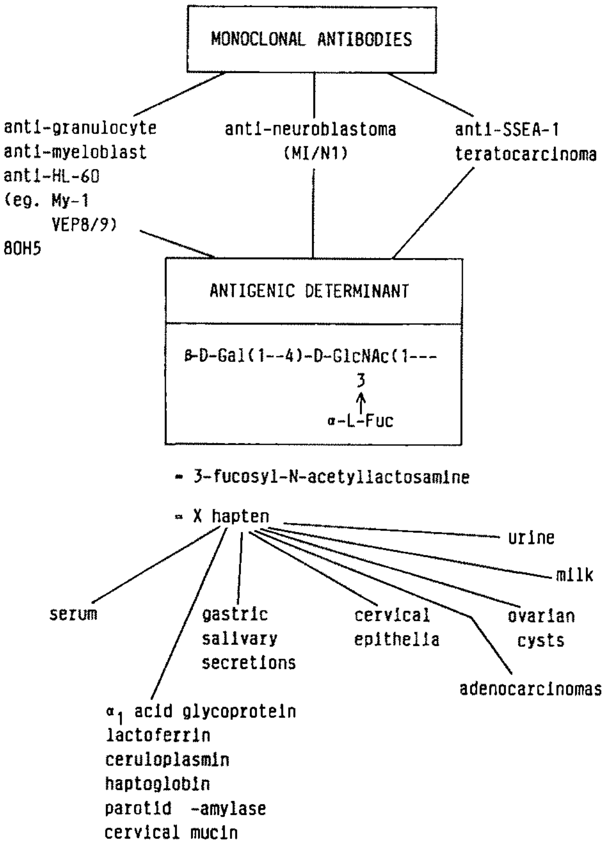

Fig 1. Widespread expression of the X hapten antigen, 3-fucosyl-N-acetyllactosamine.

Finally, McCulloch argues that the credibility of the existence of misprogrammed phenotypes is reinforced by the finding that AML patients with such aberrant cells have an inferior prognosis.[59] Even if we accept that the clinical observation, based upon rather few patients (a third of whom were unresponsive and in relapse at the time of study), is correct, the argument is itself unacceptable. A particular phenotypic constellation of markers may well provide a prognostic correlate and, in one sense, is therefore real rather than imaginary; whether that set of markers is normal or bizarre in the context of normal hematopoiesis is an entirely separate issue.

The difficulties pervading these studies, and many others concerned with leukemic cell phenotypes, revolve around presumptions made both about the specificity of markers or reagents used and of the anticipated phenotypes of normal equivalent cells. Three technical problems seem to stand out:

1. An insufficient recognition of the limited screening and often misleading nomenclature that has been applied to many antibodies prior to their widespread availability is the first technical problem. With more stringent and extensive specificity evaluation, it becomes evident that remarkably few antigenic determinants appear to exist that are entirely

restricted to a given cell type or lineage. The exclusive characteristics of cells may lie more in their composite mosaic of gene expression within which a small number of specialized function-related molecules may represent unique identity tags.

Clear examples of this type of problem are provided by studies with the T cell–associated markers identified by the monoclonal antibodies OKT9 and OKT10 (and other equivalent antibodies) These were raised against thymocytes (and T-ALL cells) and reported to identify thymocyte-associated molecules and discrete stages of T cell differentiation.[77,78] Although the original data are not refuted, it was another two years before it was widely appreciated that OKT9 and OKT10 were not T cell–specific structures but were glycoproteins with widespread expression associated with cell activation. T10 is expressed on hematopoietic cell progenitors and activated mature lymphocytes and in plasma cells,[79,80] and the T9 structure is the transferrin receptor associated ubiquitously with proliferation in vertebrate cells.[81] Similarly, the IL2 receptor identified by the anti–T cell activation antigen (anti-TAC)[82] was widely anticipated to be T cell lineage specific but is now clearly demonstrated to be expressed on some activated normal B cells and B leukemia cells.[83,84]

2. A common presumption among users of monoclonal antibodies is that these reagents are monospecific and will react with only a single determinant. This view contradicts one of the fundamental tenets of immunology. Antigenic specificity is never absolute and is a matter of relative affinity of antibody-combining sites. Antibodies, whether derived from cloned hybridomas or not, will be potentially able to cross-react with a wide variety of related and unrelated structures and, in addition, may bind via their Fc region rather than through the antibody-combining sites. The only safeguards against these problems are to know something about the chemical characteristics of the primary antigenic epitope recognized by the antibody and the structure(s) with which it is associated both in the normal and unexpected circumstance and also to use immunoglobulin class-specific controls for binding studies. Several of the aforementioned studies (Table 1) lack appropriate controls, and in only few cases has biochemical similarity or identity to the primary antigen been established.[38,44]

3. Insufficient knowledge of the immunophenotypes of normal lymphocyte subsets and the various stem cell/progenitor cell populations to which leukemias or lymphomas may correspond severely restricts the interpretation of leukemic cell phenotypes. Although this represents a considerable handicap, the identification of apparently novel markers on subsets of leukemias and lymphomas has, paradoxically perhaps, been successfully exploited to identify relatively infrequent normal cells and molecules associated with them that would otherwise have been inaccessible. Pertinent examples of the latter include identification of cells of the common ALL phenotype in normal bone marrow and fetal liver,[15,23] the B-CLL equivalent in lymph node,[74] the Sternberg-Reed (Hodgkin's) cell equivalent (reactive with antibody Ki-1) in normal lymph nodes,[85] the Burkitt's lymphoma antigen in normal lymph node germinal centers,[86] and the discovery of a stem cell/multipotential progenitor cell–associated glycoprotein based upon selective expression of an antigenic determinant (detected by the antibodies MY10, 3C5) shared by immature lymphoid and myeloid leukemias.[87–89]

We conclude that the evidence presented so far for misprogramming of differentiation or lineage infidelity of gene expression as a consistent feature of leukemia is in part invalid and unconvincing overall. We do not consider the issue clear-cut or resolved, however, since some examples of apparent infidelity are difficult to refute on the grounds of reagent specificities (see the preceding material), and the counterargument for fidelity, though compelling, could be biased by emphasis on lymphoid malignancies or selective use of markers that are subject to very stringent control following lineage commitment.

A more particular reason for expressing this reservation, however, concerns considerations of acute leukemias that might arise in cells that are not themselves committed to a single lineage and whose progeny also become arrested at a very early stage of hematopoiesis. Since we are still ignorant of the mechanisms by which bipotential or multipotential cells adopt lineage options available to them, it is premature to presume that all genes whose activity is normally associated with particular individual lineages will be expressed exclusively and in an all-or-nothing fashion.

PROMISCUITY NOT INFIDELITY OF GENE EXPRESSION IN ACUTE LEUKEMIA AND IN NORMAL HEMATOPOIESIS?

Much of the argument surrounding the varied interpretations of leukemic cell phenotypes involves the presumption that all normal hematopoietic and lymphoid cells show strict lineage specificity. This view unfortunately embodies a rather circular argument since the discovery that a marker is not, after all, lineage specific may disqualify it as an individual lineage indicator. Additionally, monoclonal antibodies raised against leukemic cells and found on initial screening to bind to both lymphoid and myeloid cells have frequently been considered of only marginal interest. As McCulloch points out,[59] there is sound reason to believe that lineage fidelity is maintained for postcommitment events, but considerable uncertainty pertains to earlier events. It is possible that some markers that are exclusively expressed in a lineage-restricted fashion on precursor cells committed to a single lineage are also transiently coexpressed on some or all multipotential cells and perhaps briefly on the progeny of these cells following the initiation of commitment but prior to full or irreversible determination. Could not, therefore, some limited degree of lineage promiscuity precede lineage fidelity as a normal course of events? If this were correct and a leukemia arose in such a precommitment phase of hematopoiesis and was subject to a relatively stringent maturation arrest, then appropriate marker analysis might reveal mixed lineage phenotypes on individual cells (Fig 2). Fidelity (ie, faithfulness to the original) would be preserved in such leukemias as lineage promiscuity but easily misread as lineage infidelity.

A similar argument with respect to normal hematopoiesis

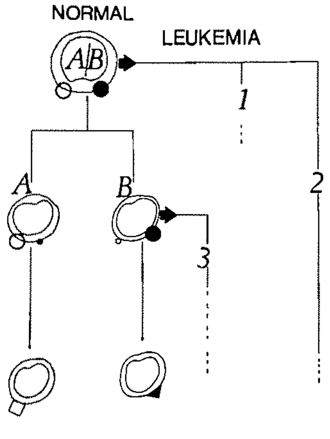

Fig 2. Restricted promiscuity of lineage-associated gene expression in hematopoiesis and leukemia. Key: A/B, bipotential progenitor cells; A B, unilineage-restricted progenitor cells; ● O, early lineage markers functionally involved in the commitment process; • o, residual expression of early markers in inappropriate lineage (relics); □ ▲, late markers involved in mature cell function; ➧ target cell for leukemogenesis; and ———-, maturation of leukemia clone (in vivo). A bipotential progenitor is shown coexpressing early (● O) but not late (□ ▲) markers of lineages A and B. The early markers may be functionally involved in the commitment process (see text). Not all multipotential (A/B) cells need express both markers simultaneously, especially if the activation process is stochastic. Immature cells committed to lineage A or B may still express, at a low level, the inappropriate gene product as a relic of parental promiscuity (small symbols, • o, on A B). The phenotypic pattern of gene expression with respect to these same markers in leukemia depends upon the level of target cell transformation (and clonal selection) and the maturation competence (in vivo) of the leukemic clone. Three types of leukemia are indicated in the Fig. In 1 and 2, the target cell is a bipotential progenitor (A/B). In leukemia 1, differentiation arrest is stringent; in leukemia 2, maturation is relatively normal (compare chronic granulocytic leukemia) [CGL]). B lineage-restricted cells are indicated as the target for leukemia 3. In leukemia, lineage promiscuity of the phenotype is most likely to be found in leukemia type 1.

was proposed by Till[90] who suggested that many lineage-associated markers might be coexpressed at a low level on multipotential progenitors and then selectively lost as cells differentiate and mature. Berridge and Okech subsequently produced some experimental support for this concept using absorbed heteroantisera to murine hematopoietic cells.[91] Although it is conceivable that all potentially available genes are expressed at a low level in progenitor cells, in its extreme form this hypothesis is unlikely to be correct since several lineage- and maturation-associated markers are undetectable on multipotential progenitors (eg, CALLA, glycophorin, T3). Nevertheless, limited or selective promiscuity could occur with respect to genes that are among the first to be expressed in a lineage and whose activity is perhaps functionally involved in lineage commitment (Fig 2).

IMMUNOGLOBULIN AND T CELL RECEPTOR GENE REARRANGEMENT AND EXPRESSION IN ACUTE LEUKEMIAS

In considering the possibility of limited promiscuity of gene expression in early hematopoiesis, we have in mind particularly the finding of immunoglobulin gene rearrangement and/or expression in T cell leukemias[52–54] and myeloid leukemias[55–57] and T cell receptor gene rearrangement and/or expression in some non–T cell leukemias.[58] These genes code for protein molecules with a known function that is cell type–unique in the same sense that hemoglobin is a specialized product of red cells. It is therefore rather striking to find that cells expressing one of these molecular markers may have a composite phenotype indicating that it belongs to a lineage not normally associated with rearrangement or expression of the gene in question.

A clue to the possible significance of these unexpected observations comes from a more detailed scrutiny of their molecular nature. Earlier studies in the mouse demonstrated that normal mouse thymocytes as well as some cytotoxic T cell clones, leukemic T cells, and myeloid cells have immunoglobulin heavy-chain gene rearrangements.[92–96] Transcripts of various sizes were also reported, and in one case these were shown to result from DJ joining in the absence of V regions.[95] Parallel studies on Abelson virus–transformed B cell precursors in fetal liver by Alt and colleagues[97,98] also revealed that DJ joining, with a corresponding truncated messenger RNA (mRNA) and protein, probably precedes recombination involving V region genes in normal B cell ontogeny. Yancopoulos and Alt also report that transcription of unrearranged V_H gene segments is prominent in cells undergoing V_H-to-DJ_H rearrangement and, in contrast to DJ_H rearrangement, is B cell specific.[99] In our studies on thymic ALL, three out of 13 cell lines and fresh samples investigated had a single μ gene allele rearranged.[53] Subsequent analysis of these rearrangements were suggestive of DJ joining (Molgaard and Ford, unpublished observations, 1985). Significantly, no non–B cell leukemias have been reported with rearrangement of κ or λ light-chain genes—events that occur later in pre–B cell ontogeny than rearrangement of both heavy-chain alleles.[52]

A very similar story is now emerging with respect to the T cell receptor β chain gene.[100] The latter has an immunoglobulin-like VDJC region suprastructure[101,102] and undergoes clonal rearrangement that can be visualized on leukemic cells by Southern blot analysis of DNA.[103] Data from both mice[104–107] and humans[106] indicate that immature thymocytes, both normal and leukemic, transcribe a 1.0kb mRNA, which is probably the product of a DJC β gene lacking a V region. Contrary to the results of Royer et al,[107] we find that the most immature T-ALL we can identify (with the phenotype: T11 + or −, T6−, T3−) have β gene rearrangement and 1.0kb transcripts.[108] Significantly, however, some of these leukemias also have a μ gene rearrangement.[108] Moreover, we also detect β gene rearrangement and/or a 1.0kb transcript of the β gene in a few leukemias that are immature myeloid or pre-B in composite phenotype.[58]

One explanation offered for these observations is that in T and B cell precursors there may be "cross talk" of the recombinases or other enzymes involved in DJ joining of immunoglobulin and the T cell receptor β gene.[109] Although this seems a plausible hypothesis, it raises the intriguing question of what makes a T cell a true T cell and a B cell a true B cell. One possibility is that DJ joining can occur in uncommitted cells and function as a necessary but insufficient genetic step in lymphoid lineage commitment. Subsequent successful recombination with a V region may then produce a protein product that irreversibly commits a cell to the B or T pathway in part by switching off further rearrangements of genes belonging to the alternative pathway and in a similar manner repress rearrangements of its own alternative allele to ensure allelic restriction of the product.[99,110,111] Unsuccessful recombination with the VIg or V β gene might permit alternative lineage possibilities to be adopted (ie, including myeloid). Since most myeloid and B lineage leukemic cells do not show evidence for DJ β rearrangement (which should be irreversible and hence detectable), we conclude, however, that lineage promiscuity with respect to this marker is not a necessary or even very common event in multipotential stem cells.

OTHER EARLY MARKERS OF HEMATOPOIETIC DIFFERENTIATION

The activity of other lineage-associated genes might similarly be required as part of the initiation process of commitment and coexpressed in some multipotential cells. We might expect this to be less likely for lineage-associated markers that arise during maturation than for molecules that arise and are expressed early in a lineage. Two early markers of human hematopoietic cells that are interesting in this respect are TdT and the T lineage-associated antigen gp40/CD-7 detected by the monoclonal antibodies 3A1,[46] WT1,[45] and Leu-9.[112]

TdT is expressed in leukemias and normal cells of the pre-B and pre-T (thymic) phenotype, is absent in mature lymphocytes,[113,114] and is postulated to play a role in increasing the diversity of immunoglobulin and T cell receptor genes by the random addition of nucleotides in the N region.[115,116] Although TdT has proved a very useful marker for acute lymphoblastic leukemia and lymphoid blast crisis of CGL, its expression is not limited to ALL. Several reports of TdT-positive AML have been published (Table 1), and in two extensive surveys of acute leukemias, 5% to 10% of cases of AML were found to be TdT-positive.[48,49] In several individual cases it has been unambiguously demonstrated that TdT and a myeloid marker (eg, myeloperoxidase or myeloid antigen) coexist in the same cells.[47,50,51] We have been reluctant to refer to this as lineage infidelity, however, since we have had no way of assessing the TdT status of appropriate control cells. It is conceivable that TdT could be induced very early in hematopoiesis in preparation for the modification of immunoglobulin and T gene rearrangements but be carried over and transiently expressed in some cells that adopt myeloid commitment. The latter might, especially if arrested in their maturation, continue to express TdT as a relic of their prior promiscuity. In contrast to TdT-positive AML, no TdT-positive CGL have been recorded in chronic-phase granulocytes despite the origin of this leukemia in pluripotential stem cells. Blast crisis of CGL that arises in the progenitor compartments with associated maturation arrest can, however, be TdT-positive.[49,117,118] We assume, therefore, that with progressive maturation of leukemic or normal cells expression of any inappropriate genes could be switched off.

Although there is very little evidence for expression of most T or B cell maturation-linked markers (eg, T3, B4) on myeloid leukemia cells, we were struck by the observation that the T lineage-associated antigen that appears to be expressed before all other described T markers in T cell differentiation—gp40/CD-7—is also coexpressed on 5% to 10% of myeloid leukemia cells.[45,46] These were not coincident with the TdT-positive cases.[45] The binding of anti-gp40 antibody to leukemic myeloid cells was ascribed to Fc activity,[46] and although this may have been the case for those AML with a monocytic component, we were able to demonstrate the presence of the gp40 molecule on leukemic myeloblasts.[44] When normal multipotential myeloid progenitors were screened using the fluorescence-activated cell sorter,[119] none had a strong or unequivocal expression of the CD-7 antigen, but a proportion (10% to 23%) of colony-forming cells (CFU-mix, BFU-E, CFU-meg, and CFU-GM) were separated into the weakly staining fraction. These observations are difficult to interpret without any clues as to the function of the CD-7 molecule. Expression of the latter may, however, like DJ rearrangements and TdT, be a marker for lymphoid lineage (T in this case) initiation or availability expressed prior to irreversible commitment.

MODELS OF LINEAGE COMMITMENT AND DIFFERENTIATION

These issues impinge directly on fundamental questions of hematopoietic differentiation and cell type–specific control of gene transcription. Several models for self-renewal and differentiation of multipotential stem cells have been proposed.[120] The major competing models of hematopoietic differentiation predict that either (1) adoption of a lineage commitment at a genetic level is indifferent to external, directive influences and follows an intrinsic program that is either stochastic (probabilistic) or deterministic (ordered) in nature[120–124] or (2) that the choice of commitment to a particular lineage is intrinsically flexible, the outcome being determined or imposed by external, microenvironmental influence,[125] eg, growth factors[126–127] and/or stromal elements[128,129] or other positional information.[130]

If, as we propose, certain early lineage-associated markers are promiscuously coexpressed on bipotential or multipotential cells (and their corresponding leukemias), then these might themselves function to advertise the accessibility of particular lineage options. Such an arrangement could provide a compromise between the two conflicting theories of commitment by incorporating features of both in sequence. Activation of particular early genes could arise intrinsically, in a programmed or randomly generated fashion, and indicate spontaneous initiation of the commitment process in one or more lineages. The particular lineage option endorsed in individual cells might subsequently be determined both by the particular pattern of markers expressed (and hence lineages available) and by the balance of external influences. We are not aware of any data that would refute this suggestion.

In respect to this model, prime candidates for promiscuous expression in addition to DJ joining in Ig heavy-chain genes and the T cell receptor genes as previously discussed would be cell surface receptors for factors that regulate growth and maturation early in a lineage, eg, granulocyte/macrophage (GM)-CSF and as yet undiscovered regulators of early lymphoid development. Both Till[90] and van Zant and Goldwasser[126] have previously suggested that uncommitted progenitors might be expected to express concomitantly or sequentially receptors for growth factors that regulate growth and maturation in a lineage-restricted fashion. Some functional studies by Metcalf and Burgess involving single-cell manipulations[127] and other studies on enriched progenitor populations[131] suggest that this could well be the case for GM colony-forming cells. Since several hematopoietic growth factors have recently been molecularly cloned,[132,133] it should soon be possible to test in vitro whether their receptors are coexpressed on bipotential or multipotential cells prior to irreversible commitment. In this context comparisons with other receptor-mediated responses will be useful. Some hormonal ligands (eg, insulin, vasopressin) not only regulate the level of their complementary receptors in target cells (and hence the cells' intrinsic sensitivity to a repeat stimulus) but can concomitantly induce the transmodulation of receptors for other ligands on the same cell.[134] This may provide a general mechanism for preempting a competing pathway of cell regulation. It is relevant also to note that lineage choice can be regulated or directed by external signals in other cellular systems involving bipotential cells (in vitro), eg, astrocyte *v* oligodendrocyte differentiation in glial progenitor cells[135] and cholinergic *v* adrenergic differentiation in ganglion cells.[136]

These issues will be more amenable to direct experimentation when multipotential stem cells retaining differentiation capacity can be selected, cloned, and manipulated more effectively in vitro. It may soon be possible, however, to test the validity of the limited promiscuity idea, some predictions of which might include the following: (1) Clonogenic cells in some cases of acute leukemia should coexpress early markers of more than one hematopoietic lineage in contrast to their more mature descendants and nonhematopoietic tumor cells, which should not. (2) Some normal, multipotential stem cells should coexpress at detectable levels some early differentiation-associated antigens or growth factor receptors of more than one lineage (eg, CD-7 plus GM-CSF receptors in various combinations) but not markers associated with later maturational stages within particular lineages (eg, CD-1/T6 plus MY9 or glycophorin A). Additionally, at least a fraction of multipotential progenitors should produce abbreviated transcripts of immunoglobulin heavy-chain or the T cell receptor β chain (with or without detectable gene rearrangements) or both, and at least a few normal, myeloid lineage progenitors should express TdT. (3) Some relic, at least of abortive or partial DNA rearrangements of immunoglobulin (DJ_H) or T cell receptor chain (DJ) genes, should be detectable in mature hematopoietic cells (lymphoid and myeloid) of the inappropriate type. These rearrangements should not include heavy-chain V region genes or light-chain genes. (4) Some cells expressing early markers of two lineages should retain the capacity to adopt either lineage.

Clearly, such experiments will require judicious choice of markers and growth factor protein produced from cloned DNA as well as purified progenitors and highly efficient clonal assays.

NOTE ADDED IN PROOF

Two other groups have recently reported clonal rearrangement of Ti β genes in some B cell lineage leukemias: O'Conor et al, Lancet 1:1295, 1985, and Pelicci et al, J Exp Med 162:1015, 1985.

Part of the Activating Cross-Linked Immunoglobulin G Is Internalized by Human Platelets to Sites Not Accessible for Enzymatic Digestion

By Martin O. Spycher and Urs E. Nydegger

The differential uptake of tritium-labeled immunoglobulin G (IgG) cross-linked with bisdiazonium-benzidine (BDB) (^{3}H-BDB-IgG) by washed, pooled human platelets to sites inaccessible to pronase digestion was tested. Up to 52% of the ^{3}H-BDB-IgG associated with platelets at 37 °C resisted pronase treatment, whereas only 23% of the cross-linked IgG associated with platelets at 4 °C, or at 37 °C but in the presence of deoxyglucose/antimycin A, remained refractory to pronase. This effect was not due to platelet agglutination. Pronase resistance reached a maximum after a 60-minute incubation period at 37 °C. With increasing ^{3}H-BDB-IgG input, both the total cross-linked IgG associated with platelets and the fraction resistant to pronase digestion approached saturation at 4 °C, but not at 37 °C. The proportion of ^{3}H-BDB-IgG bound to platelets at 4 °C that was resistant to pronase treatment increased by 13% within five minutes of warming the platelets to 37 °C. Pretreatment of platelets with 10 mmol/L acetylsalicylic acid (or 10 μmol/L prostaglandin E_1) prior to the addition of ^{3}H-BDB-IgG led to a 74% (95%) inhibition of the ^{3}H-BDB-IgG-induced ^{14}C-serotonin release, but to only a 44% (49%) inhibition of pronase-digestible bound ligand. In contrast, pretreatment with 10 μmol/L cytochalasin B led to a mere 17% reduction of ^{14}C-serotonin release, whereas acquisition of resistance to pronase digestion by the bound ^{3}H-BDB-IgG was inhibited by 90%. Incubation of platelets at 37°C with ^{3}H-BDB-IgG and removal of unbound material prior to the addition of prostaglandin E_1 or deoxyglucose/antimycin A had little effect on the susceptibility of platelet-associated ^{3}H-BDB-IgG to pronase, whereas the addition of cytochalasin B to ^{3}H-BDB-IgG-treated platelets resulted in greatly increased susceptibility of the platelet-associated ligand to pronase. Thus, after binding, ^{3}H-BDB-IgG becomes transferred in an energy-dependent process to pronase-resistant cellular sites, most likely to the open canalicular system.

THE INCREASED ASSOCIATION of immunoglobulin G (IgG) with human platelets in such clinical disorders affecting platelets as idiopathic thrombocytopenic purpura[1,2] or some cases of systemic lupus erythematosus,[3] myeloproliferative disease,[3] septicemia,[4] Hodgkin's disease,[5] and malignant tumors[6] is now well documented. Current techniques cannot distinguish whether platelet-associated IgG is present in the form of platelet-directed alloantibodies or autoantibodies or as bound immune complexes. In addition, it has been reported that platelets contain intracellular IgG because higher amounts of IgG can be detected in lysates of platelets than on the intact cell.[7] This may be the main reason why methods that use intact rather than lysed platelets for measuring platelet-associated IgG generally result in lower values of platelet-associated IgG.[8–11]

Complexed IgG activates washed human platelets by binding to a putative Fc receptor. This was suggested from the finding that complexed Fc fragments of IgG, but not immune complexes containing F(ab')$_2$ fragments of antibody-activated platelets,[12,13] and only monomeric IgG and Fc fragments thereof, but not F(ab')$_2$ fragments, inhibited activation of the platelets induced by complexed IgG.[13–15]

Initial studies of the binding of bisdiazonium-benzidine (BDB)-cross-linked IgG (BDB-IgG), a potent activator of human platelets, or monomeric IgG to washed human platelets revealed binding that was not saturable and was mostly irreversible.[14–16] Saturable and reversible binding has been shown to platelets of dimeric or higher-order polymeric IgG[1] aggregates at 4 °C[17] or of BDB-IgG or monomeric IgG in the presence of deoxyglucose and antimycin A at 37 °C.[16] This suggested that mere receptor-ligand binding can only be studied on metabolically inhibited platelets and that IgG could be internalized by active platelets at 37 °C. We studied the manner by which BDB-IgG or monomeric IgG were handled by washed, pooled human platelets by making use of various inhibitors of platelet function and studying differential accessibility of noninternalized *v* internalized IgG to pronase.

MATERIALS AND METHODS

Buffers. Buffer A consisted of 90 mmol/L Tris- (hydroxymethyl) aminomethane (Tris), 30 mmol/L NaCl, 10 mmol/L EDTA, and 6.25 mg/mL bovine serum albumin (BSA), pH 7.6. Buffer B consisted of 46 mmol/L Tris, 7.5 mmol/L *N*-tris (hydroxymethyl) methyl-2-aminoethane sulfonic acid (TES), 15.5 mmol/L KCl, 78 mmol/L NaCl, 5 mmol/L EDTA, and 3.13 mg BSA, pH 7.4.

Platelet preparations. Platelet-rich plasma was prepared from citrated blood as previously described.[18] Two parts of platelet-rich plasma were mixed with one part of 30 mmol/L citric acid, 3 mmol/L KCl, 102 mmol/L NaCl, and 4.8 mmol/L glucose, pH 6 5, after adjustment of the pH to 6.5 Thereafter, platelet-rich plasma was incubated at 37 °C for 30 minutes, and platelets were washed three times by repeated centrifugation for ten minutes at 1,200 g at room temperature and resuspension in washing buffer containing 3 mmol/L 2(*N*-morpholino) ethane sulfonic acid (MES), 3 mmol/L KCl, 147 mmol/L NaCl, and 4 8 mmol/L glucose, pH 6.5. Finally, they were resuspended in 28 mmol/L TES, 3 mmol/L KCl, 108 mmol/L NaCl, and 25 mmol/L glucose, pH 6.8, at a concentration of 5.1 × 10^9/mL and incubated for one hour at room temperature. In experiments with deoxyglucose- and antimycin A–treated platelets, glucose was omitted in the third washing step, and 25 mmol/L deoxyglucose and 1 μmol/L antimycin A instead of 25 mmol/L glucose were included in the final resuspension buffer.

Protein Preparations and Labeling With Tritium. The IgG was obtained by cold ethanol fractionation and contained IgG:IgM:IgA in a ratio of 600:8:1. It was cross-linked with BDB according to Pfueller et al.[14] To remove IgG not cross-linked and smaller aggregates, BDB-IgG was gel filtered on a Biogel A-5m column (Bio-Rad Laboratories; Richmond, Va), and only protein eluted in the void volume consisting of aggregates with ten to 30 IgG molecules[14] was used. BDB-IgG, monomeric IgG (IgG obtained from the upper half of the contents in a test tube after centrifugation at 100,000 g for one hour at 4 °C), and human serum albumin were labeled with ^{3}H by reductive methylation as described.[19] In brief, 3 to 4 mg of protein in 500 μL 10 mmol/L Na-phosphate and 0.14 mol/L NaCl, pH 7.0, were mixed at 4 °C with 800 μL of 0.5 mol/L Na-diethylborate, pH 9.0, and 155 μL of fresh 20 mmol/L formaldehyde, and 30 seconds later, 100 μL of ^{3}H-NaBH$_4$ (approximately equal to 5 mCi in 10 mmol/L NaOH, 8.8 Ci/mmol/L; New England Nuclear, Boston) were added. After 20 minutes at 4 °C, 20 μL of 0.1 mol/L NaBH$_4$ was included, and after a further 20 minutes, 20 μL of glycerine was added and the pH adjusted to about 7 with 20% acetic acid. After exhaustive dialysis against 10 mmol/L Tris-HCl and 0.14 mol/L NaCl, pH 8.0, labeled protein was stored at −70 °C in aliquots. Specific activity was within the range 0.8 to 1.8×10^5 cpm/μg.

Measurement of labeled protein associated with washed platelets and pronase treatment. Before use, ^{3}H-BDB-IgG and BDB-IgG were centrifuged for ten minutes at 4 °C and 40,000 g to remove insoluble material, and monomeric IgG preparations were centrifuged at 100,000 g at 4 °C for one hour, whereupon only the upper half of the supernatant was used to eliminate self-aggregated IgG as far as possible. Four parts buffer A were incubated at 37 °C or 4 °C with two parts washed platelets (5.1×10^9/mL) and one part 0.15 mol/L NaCl with slow stirring. After 5 minutes, one part labeled protein was added and incubation continued with slow stirring for 30 minutes at the temperature indicated. Then all tubes were cooled to 4 °C and centrifuged at this temperature for 15 minutes at 2,000 g. The supernatants were discarded and the sediments resuspended with eight parts cold buffer B Duplicate 600-μL aliquots of each sample were incubated either with 200 μL BSA (20 mg/mL in 0 15 mol/L NaCl) or with 200 μL pronase (20 mg/ml in 0.15 mol/L NaCl, 77 PUK [enzyme activity liberating folin positive amino acids] per mg; Sigma Chemical Co, St Louis). Digestion of surface-bound ligand was allowed to proceed usually for four hours at 4 °C, a time lag considered to be optimal because incubation for a further five hours led only to a 4% decrease in remaining platelet-associated radioactivity and because incubation of platelets with pronase for longer time periods (16 hours at 4 °C) resulted in some platelet damage as determined by the release of ^{14}C-serotonin and ^{3}H-adenine. After incubation of the platelets with pronase and BSA, 150 μL of a mixture of dinonylphthalate:dibutylphthalate (1:2.56) were added, and the tubes were centrifuged at 11,000 g for 30 seconds, separating the platelets from the water phase through the phthalate mixture. Aliquots of the supernatants were counted and the tubes inverted. After removing traces of supernatant using absorbent paper, 150 μL 0.5% Triton X-100 (Bio-Rad, Richmond, Calif) and two drops of xylol were added to the sediments before sonification with a Branson sonifier (Branson Sonic Co, Danbury, Conn) Solubilized platelets were transferred to a counting vial and radioactivity measured in a Packard TriCarb 2450 Liquid Scintillation Spectrometer (Downers Grove, Ill). Inhibitors of platelet activation by ^{3}H-BDB-IgG were added to the incubation mixture instead of the one part 0.15 mol/L NaCl. Experiments were always done in duplicate, which usually did not differ from one another by more than 5%.

Calculations. Normally the amount of platelet-associated ligand remaining after BSA or pronase treatment was calculated first by using the specific activity of the labeled compound. The percentage of pronase-resistant protein was then calculated as 100 times the ratio between the platelet-associated protein in the presence of pronase and in the presence of BSA. In the initial experiments, 200 μg/mL of inulin and 43 μCi of ^{14}C-hydroxymethylinulin (30 μCi/mL, 2.14 μCi/mg; Amersham, England) were included in buffer B to correct for labeled protein trapped within the platelet sediment but not associated with the platelets themselves Calculations were made as previously described[14] These corrections were found to be irrelevant, and therefore the inulin preparations were omitted in later experiments.

Measurement of ^{14}C-serotonin release by washed platelets Platelets were labeled with ^{14}C-serotonin (5-hydroxy (side chain-2-^{14}C)-tryptamine creatinine sulfate, 55 mCi/mmol/L [Amersham, England]) by incubation with the labeled compound at a concentration of 125 nCi/mL of platelet suspension for one hour at room temperature. On an average, 92% of the ^{14}C-serotonin was taken up by the platelets. To measure the release of ^{14}C-serotonin induced by ^{3}H-BDB-IgG, incubations were done in the same way as for measurement of ^{3}H-BDB-IgG association, but imipramine (2 μmol/L final concentration) was added to prevent reuptake of released ^{14}C-serotonin. After the indicated incubation period at 37 °C or 4 °C, 400 μL of the mixture was centrifuged at 11,000 g for 30 seconds, and 200 μL of supernatant was added to 2 mL of scintillator to be counted then in the Packard liquid scintillation spectrometer. The formula for the calculation is as follows: ^{14}C-serotonin released (%) = $[(X - B)/(T - B)] \times 100$, where X is the cpm of the sample after centrifugation, T is the total cpm contained in 200 μL before centrifugation, and B is the control—cpm of 200 μL of supernatant after centrifugation but without ^{3}H-BDB-IgG.

Other methods. (1) Platelets were counted in a TOA platelet counter (TOA, Medical Electronics Co, Kobe, Japan) according to the instructions of the manufacturer. (2) To measure possible degraded products of platelet-associated ^{3}H-BDB-IgG, platelets incubated with ^{3}H-BDB-IgG at 37 °C and 4 °C for 30 minutes were solubilized with 1% sodium dodecyl sulfate (SDS; Bio-Rad, Richmond, Calif), one aliquot was immediately counted, and trichloroacetic acid was added to the other aliquot (10% final concentration). After a four-hour incubation period at 4 °C, the samples were centrifuged, and radioactivity in the supernatants was determined.(3) Slab gel electrophoresis of SDS-solubilized and reduced platelets previously incubated with ^{3}H-BDB-IgG at 4 °C or 37 °C in a 5% to 15% gel was done according to Laemmli,[20] and fluorography of the gels was performed as previously described.[19] (4) Prostaglandin E and cytochalasin B were obtained from Sigma Chemical Co, St Louis. They were dissolved in dimethylsulfoxide to a concentration of 10 mmol/L and stored at −20 °C. Dilutions were made with 0.15 mmol/L NaCl. All other substances were of reagent grade. (5) Protein concentrations were determined with a modified Lowry method as described[15] using BSA as a standard.

RESULTS

Pronase susceptibility of ^{3}H-BDB-IgG or ^{3}H-monomeric IgG (^{3}H-mIgG) associated with washed human platelets at 4 °C or 37 °C. In a first step, the capacity of platelets to take up ^{3}H-BDB-IgG was evaluated under three different conditions: at 37 °C, at 4 °C, and at 37 °C after treatment with deoxyglucose/antimycin A. Figure 1A shows that platelets were able to take up more ^{3}H-BDB-IgG at 37 °C than at 4 °C (0.60 μg compared to 0.38 μg), and in the presence of deoxyglucose/antimycin A, association at 37 °C was reduced to 0.20 μg.

The capacity of pronase to remove platelet-associated ^{3}H-BDB-IgG was also assessed: 52% of the ^{3}H-BDB-IgG

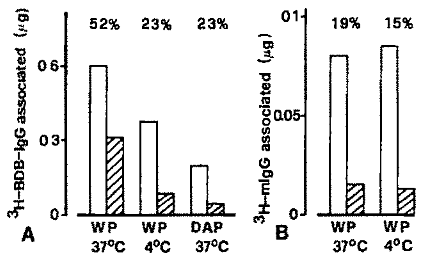

Fig 1. (A) Internalization of ^{3}H-BDB-IgG by washed human platelets as determined by the loss of accessibility to pronase. Washed platelets (WP) or deoxyglucose/antimycin A–treated platelets (DAP) were incubated with ^{3}H-BDB-IgG (12 µg/mL) at 37 °C or 4 °C for 30 minutes. After washing at 4 °C and resuspension in buffer without ^{3}H-BDB-IgG, the platelets were divided into two fractions. To the first fraction 5 mg/mL pronase was added (shaded bars), to the second, 5 mg/mL BSA (open bars). After incubation for six hours at 4 °C, platelets were centrifuged through oil and the radioactivity in the sediment was determined. The ordinate represents ^{3}H-BDB-IgG associated to 7.5 × 10^8 platelets. At the top of each pair of bars, percentages of pronase-resistant ^{3}H-BDB-IgG associated to the platelets are indicated (determined as the ratio between ^{3}H-BDB-IgG associated to pronase- and BSA-treated platelets). (B) The same experiment as in Fig 1A, but washed platelets were incubated with ^{3}H-mIgG (30 µg/mL) instead of ^{3}H-BDB-IgG.

associated with platelets at 37 °C resisted subsequent pronase treatment, whereas only 23% of the ^{3}H-BDB-IgG associated to platelets at 4 °C or to deoxyglucose/antimycin A–treated platelets at 37 °C was refractory to pronase digestion (Fig 1A). Thus, at 37 °C, a 29% increase of pronase-resistant protein was found. When platelets were incubated with ^{3}H-BDB-IgG for 30 minutes at 37 °C, washed, treated with deoxyglucose/antimycin A at room temperature for one hour, and then further incubated at 37 °C for 30 minutes, they still carried 70% of the initial pronase-resistant ^{3}H-BDB-IgG. Thus, the deoxyglucose/antimycin A treatment was unable to make substantial amounts of pronase resistant ^{3}H-BDB-IgG available to pronase digestion. When experiments were carried out with ^{3}H-monomeric IgG (^{3}H-mIgG) instead of ^{3}H-BDB-IgG, they revealed that incubation at either 37 °C or 4 °C allowed similar amounts of ^{3}H-mIgG to become associated with platelets in a way that was highly susceptible to pronase treatment at both temperatures (Fig 1B). To exclude self-aggregated IgG in the mIgG preparation as much as possible, the IgG preparations were always centrifuged immediately before use for one hour at 100,000 g and 4 °C, and only the upper half of the supernatants was used.

Although all experiments were done in the presence of 5 mmol/L EDTA, which is known to prevent platelet aggregation, we investigated whether the decreased pronase susceptibility of ^{3}H-BDB-IgG associated to platelets at 37 °C was possibly due to the entrapment of protein within microscopic aggregates or agglutinates. In fact, pronase resistance of labeled, platelet-associated mIgG was as low as indicated in Fig 1B whether or not 20 µg/mL BDB-IgG was included in the samples during the 37 °C incubation period to activate the platelets, and the same result was obtained using labeled human serum albumin instead of ^{3}H-mIgG (data not shown). This is incompatible with platelet clumping as the major reason for the increased pronase resistance of platelet-associated ^{3}H-BDB-IgG. Nevertheless, platelet activation produced by incremental amounts of ^{3}H-BDB-IgG resulted in some microscopic aggregation or agglutination even in the presence of EDTA as seen from a decrease in platelet numbers determined by electronic counting (Fig 2). However, comparison of aggregation to pronase susceptibility of platelet-associated ^{3}H-BDB-IgG revealed no correlation: 50% pronase-resistant platelet-associated ^{3}H-BDB-IgG was observed with 5 µg/mL of ^{3}H-BDB-IgG, whereas the reduction of platelet count at this concentration was only 2% (Fig 2). In addition, pronase resistance was readily saturable, whereas the reduction in platelet count progressively increased with increasing ^{3}H-BDB-IgG inputs.

The time course of the acquisition of resistance to pronase by ^{3}H-BDB-IgG associated with platelets at 37 °C and at 4 °C is shown in Fig 3. It appears that pronase resistance becomes detectable after two minutes and reaches a plateau after one hour, whereas at 4 °C, pronase was always able to remove the bulk of platelet-associated radioactivity. The same saturation characteristics were obtained when the time course of the ^{3}H-BDB-IgG association with platelets was examined after BSA or pronase treatment (data not shown).

Concentration dependence of ^{3}H-BDB-IgG binding to platelets and its susceptibility to pronase digestion. Increasing amounts of ^{3}H-BDB-IgG were incubated with washed platelets at 37 ° C or at 4 °C for 30 minutes in the presence or absence of 5 mg/mL unlabeled mIgG. Then the amount of ^{3}H-BDB-IgG associated with the platelets after the four-hour incubation with pronase or BSA at 4 °C was determined. Specific binding is referred to as the difference of the amounts of ^{3}H-BDB-IgG found associated to platelets with and without unlabeled mIgG in the system. In parallel tubes, release of ^{14}C-serotonin was measured at 37 °C (Fig 4). As can be seen, specific ^{3}H-BDB-IgG binding approached saturation at 4 °C but not at 37 °C with or without pronase treatment. Significant binding had already occurred at a very low ^{3}H-BDB-IgG concentration, which did not result in serotonin release at 37 °C. Nonspecific binding was substan-

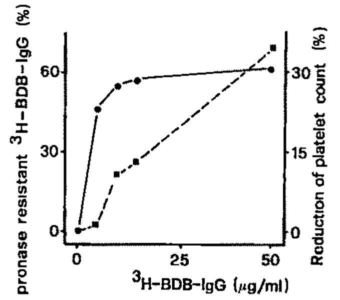

Fig 2. Comparison of the pronase resistance of platelet-associated ^{3}H-BDB-IgG with platelet agglutination or aggregation. Washed platelets were incubated with increasing amounts of ^{3}H-BDB-IgG for 30 minutes at 37 °C. After washing at 4 °C, platelets were counted on a TOA platelet counter, and pronase-resistant platelet-associated ^{3}H-BDB-IgG was determined as described in Materials and Methods. ●——●, Pronase resistance of associated C^{3}H-BDB-IgG; ■----■, reduction of platelet count.

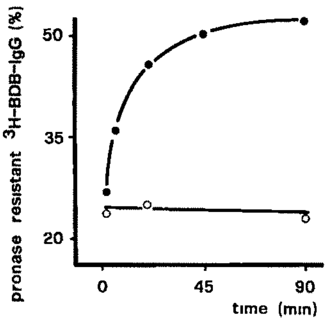

Fig 3. Time course of pronase-resistant platelet-associated ^{3}H-BDB-IgG. ^{3}H-BDB-IgG (10 μg/mL) was incubated with washed platelets at 37 °C (●) or 4 °C (○). At the indicated times, aliquots were taken and kept on ice. After the last aliquot had been taken, 5 mg/mL pronase was added to one half of each aliquot and 5 mg/mL BSA to the other, and further processing was done as described in Materials and Methods.

Table 1. Comparison of the Percentage of Pronase-Resistant ^{3}H-BDB-IgG Specifically Associated With Washed Platelets and Serotonin Release in Relation to Increasing ^{3}H-BDB-IgG Additions to Washed Platelets at 37 °C and 4 °C

^{3}H-BDB-IgG (μg/mL)	Percentage of Pronase-Resistant ^{3}H-BDB-IgG Specifically Associated With Washed Platelets at 37 °C*	4 °C	Percentage of ^{14}C-Serotonin Release at 37 °C†
4	46 (23)	23	1
13 5	54 (28)	26	10
50	77 (46)	31	38
150	72 (41)	31	49

*Experimental procedures as described in Materials and Methods. Values in brackets represent the difference of values at 37 °C and 4 °C

†Platelets incubated with ^{3}H-BDB-IgG at 4 °C did not release ^{14}C-serotonin

tial with high–^{3}H-BDB-IgG input and reached 50% of the total binding at 150 μg/mL of ^{3}H-BDB-IgG. The percentages of pronase-resistant ^{3}H-BDB-IgG specifically associated with washed platelets at 37 °C or at 4 °C are compared in Table 1 with the percentage of ^{14}C-serotonin release over the same range of ^{3}H-BDB-IgG input. It appears that at 37 °C the specific platelet-associated pronase-resistant ^{3}H-BDB-IgG as well as the serotonin release increased depending on the dose of the ^{3}H-BDB-IgG input, whereas at 4 °C, only 8% additional pronase resistance was seen with the highest input of ligand.

When platelets were treated with 100 μg/mL ^{3}H-BDB-IgG at 4 °C for 60 minutes, washed, and warmed to 37 °C for a further five- or 30-minute incubation, pronase susceptibility after both 37 °C incubation periods was decreased by 13% as compared to such susceptibility measured after the 4 °C time period. At the same time, 42% of the ^{14}C-serotonin was released by the platelets. Lower ^{3}H-BDB-IgG inputs (20 μg/mL or 50 μg/mL) resulted in no significant decrease of pronase susceptibility of associated protein whereas ^{14}C-serotonin release was below 18%.

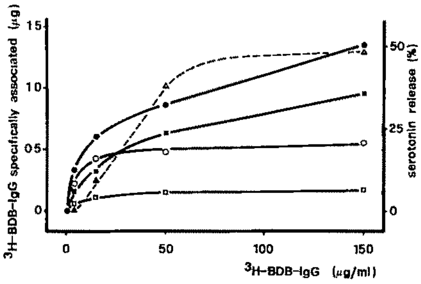

Fig 4. Dose dependence of specific ^{3}H-BDB-IgG association with washed platelets after BSA or pronase treatment (——) and simultaneous measurement of serotonin release. (---) Washed platelets were incubated with increasing amounts of ^{3}H-BDB-IgG for 30 minutes at 37 °C or 4 °C in the presence or absence of 5 mg/mL mIgG, and the amount of ^{3}H-BDB-IgG specifically associated with 7.5 × 10^8 platelets was determined. Specific association represents the difference of association measured in the presence and absence of mIgG. Key: ●, platelets incubated at 37 °C before the addition of BSA; ■, platelets incubated at 37 °C before the addition of pronase; ○, platelets incubated at 4 °C before the addition of BSA; and □, platelets incubated at 4 °C before the addition of pronase. The ^{3}H-BDB-IgG–induced serotonin release at 37 °C (from platelets prelabeled with ^{14}C-serotonin) was measured (△) in parallel tubes.

Inhibition of ^{3}H-BDB-IgG association with platelets by monomeric IgG and by reagents interfering with platelet activity at different levels. Inhibition of the ^{3}H-BDB-IgG association with washed platelets at 37 °C or 4 °C induced by incremental amounts of mIgG is shown in Fig 5. For these experiments, mIgG was added to the platelets five minutes before ^{3}H-BDB-IgG, and it can be seen that mIgG inhibits the uptake of ^{3}H-BDB-IgG by the platelets at both incubation temperatures independently whether or not pronase was added. Pronase resistance of platelet-associated ^{3}H-BDB-IgG was also inhibited by mIgG, inhibition of the ^{3}H-BDB-IgG association occurring at lower mIgG inputs than inhibition of pronase resistance (data not shown).

The effects of acetylsalicylic acid (which interferes with the prostaglandin pathway by inhibiting cyclooxygenase[21]), prostaglandin E$_1$ (which elevates the intracellular cAMP concentration[21]) and cytochalasin B (which interacts with actin[22]) on pronase susceptibility of platelet-associated ^{3}H-

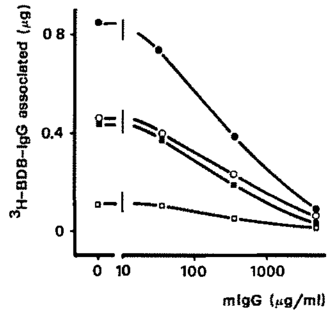

Fig 5. Inhibition by mIgG of ^{3}H-BDB-IgG association with washed platelets. Washed platelets were incubated with increasing amounts of mIgG for five minutes at 37 °C or 4 °C before the addition of ^{3}H-BDB-IgG (15 μg/mL). After a further incubation for 30 minutes at the corresponding temperature, platelet-associated protein was determined as described in Materials and Methods. For symbols see Fig 4.

BDB-IgG were studied. In a first set of experiments, washed platelets were incubated with the inhibitor for five minutes at 37 °C before the addition of ^{3}H-BDB-IgG and a further incubation for 30 minutes at 37 °C. Then the percentage of pronase-resistant, platelet-associated ^{3}H-BDB-IgG was determined. The same experiment was also conducted at 4 °C. At this temperature, at which platelets are not activated by ^{3}H-BDB-IgG, the percentage of pronase-resistant protein did not change significantly and was within a range of 18% to 23% whether or not inhibitors were present. Table 2, column 2, shows the inhibition of the increased pronase resistance of platelet-associated ^{3}H-BDB-IgG induced during the activation of the platelets at 37 °C. In parallel tubes, the ^{3}H-BDB-IgG–induced release of ^{14}C-serotonin at 37 °C was also measured (Table 2, column 4). Although acetylsalicylic acid and prostaglandin E_1 had a marked inhibitory effect on ^{3}H-BDB-IgG–induced serotonin release, their effect on preventing pronase from removing ^{3}H-BDB-IgG associated to platelets was less distinct. In contrast, addition of cytochalasin B led to an increased protease susceptibility of platelet-associated ^{3}H-BDB-IgG but had little or no inhibitory effect on ^{3}H-BDB-IgG–induced serotonin release. In a second set of experiments, platelets were incubated with ^{3}H-BDB-IgG for 30 minutes, one sample at 37 °C, the other at 4 °C; both samples were washed at 4 °C and incubated thereafter with inhibitor at the corresponding temperature for 30 minutes (Table 2, column 3). It was found that 10 μmol/L prostaglandin E_1 had no effect on the pronase resistance of platelet-associated ^{3}H-BDB-IgG, whereas increasing cytochalasin B input led to an inhibition of the increased pronase resistance of platelet-associated ^{3}H-BDB-IgG obtained at 37 °C, the extent being not so marked as the decrease observed upon simultaneous incubation of cytochalasin B and ^{3}H-BDB-IgG with platelets. Again, both inhibitors had no effect on the pronase resistance of ^{3}H-BDB-IgG associated with platelets at 4 °C.

Table 2. Effect of Inhibitors of Platelet Functions on the Resistance to Pronase of Platelet-Associated ^{3}H-BDB-IgG and the Induction of Serotonin Release by ^{3}H-BDB-IgG

	Inhibition of Pronase Resistance (%)*

*Numbers represent the percent inhibition of the increased pronase resistance of ^{3}H-BDB-IgG associated with platelets at 37 °C. This is calculated as 100 times the ratio between the difference of pronase resistant ^{3}H-BDB-IgG from samples incubated at 37 °C and 4 °C in presence of the inhibitor and the same difference without the inhibitor.

†Washed platelets were incubated with the inhibitor for five minutes before the addition of ^{3}H-BDB-IgG (30 μg/mL) and a further 30-minute incubation. Two samples were run, one at 37 °C, the other at 4 °C. Release of ^{14}C-serotonin induced by 30 μg/mL ^{3}H-BDB-IgG at 37 °C was assessed in parallel tubes. At 4 °C there was no release of ^{14}C-serotonin.

‡Washed platlets were incubated with ^{3}H-BDB-IgG at either 37 °C or 4 °C for 30 minutes, washed at 4 °C, and resuspended in buffer B before the addition of inhibitors and a further 30-minute incubation at the corresponding temperature.

Finally, we were interested to know whether platelet-associated ^{3}H-BDB-IgG is processed further by intrinsic platelet enzymes. For this purpose, ^{3}H-BDB-IgG was incubated with platelets at 37 °C and 4 °C for 30 minutes or 120 minutes, respectively; then the platelets were solubilized with SDS, and trichloroacetic acid–precipitable radioactivity was measured: no decrease in precipitable radioactivity was found. In addition, gel electrophoresis of ^{3}H-BDB-IgG obtained from the solubilized platelets and subsequent fluorography of the gel showed no degradation of the aggregated IgG into smaller components.

DISCUSSION

We demonstrate that part of aggregated immunoglobulin used for the activation of platelets becomes inaccessible to prolonged pronase digestion probably because of displacement to intracellular sites. Our findings may explain the observation that saturable and reversible association of aggregated IgG with washed human platelets can be obtained at 4 °C[17] but can only be demonstrated at 37 °C in the presence of metabolic inhibitors deoxyglucose and antimycin A.[16] Thus, evidence is provided that the engulfment of aggregated IgG taking place at 37 °C is energy dependent and does not result from either passive diffusion to pronase-inaccessible sites or entrapment within platelet aggregates or agglutinates. This is based on the following arguments: (1) EDTA (5 mmol/L), which is known to prevent platelet aggregation, was always included in the reaction mixtures. (2) Although with the addition of incremental amounts of ^{3}H-BDB-IgG to constant amounts of platelets some decrease in the platelet count occurred in the reaction tubes (Fig 2), a simultaneous evaluation of pronase resistance revealed an increase of engulfed material that already occurred at much lower ^{3}H-BDB-IgG inputs and then plateaued. In addition, the day-to-day variation in the platelet count decrease was substantial during these experiments, whereas pronase resistance remained constant within small limits. (3) There was no change in the proportion of platelet-associated labeled mIgG or human serum albumin that was resistant to pronase digestion after the addition of 20 μg/mL BDB-IgG, a concentration of BDB-IgG known to activate the platelets even in the presence of small amounts of ^{3}H-mIgG or human serum albumin. (4) The omission of stirring during the incubation of ^{3}H-BDB-IgG with the platelets did not lead to a decreased pronase resistance of platelet-associated ^{3}H-BDB-IgG (data not shown).

If such a reduction of pronase-accessible surface area by aggregation or agglutination of platelets is not the reason why part of the ^{3}H-BDB-IgG associated at 37 °C escapes pronase digestion, then the assumption appears justified that the binding of ^{3}H-BDB-IgG to the platelet plasma membrane is followed by redistribution to an area not accessible to pronase digestion. There is a difference in the extent of the ^{3}H-BDB-IgG associated with platelets and its pronase resistance depending on whether the platelets were incubated with the IgG aggregates at 37 °C or preincubated with the aggregates at 4 °C and then warmed to 37 °C after the removal of unbound material. When incubation was at 4 °C prior to warming to 37 °C, the fraction of ^{3}H-BDB-IgG that was not susceptible to pronase digestion was only increased by 13% even at the highest input of IgG aggregates (100 μg/mL), with no significant increase at lower inputs of ^{3}H-BDB-IgG. In contrast, incubation of the platelets at 37 °C with low amounts of ^{3}H-BDB-IgG (20 μg/mL) resulted in a 29% increase of pronase-resistant platelet-associated ^{3}H-BDB-IgG. Simultaneous measurement of the ^{14}C-serotonin release by platelets treated with ^{3}H-BDB-IgG at 4 °C and then warmed up revealed a reduced release compared to that measured by the incubation of ^{3}H-BDB-IgG with washed platelets at 37 °C, although the extent of reduction was not so pronounced as compared to the reduction of pronase resistance. It appears that during centrifugation after the 4 °C incubation period a considerable part of the ^{3}H-BDB-IgG is lost from its binding sites, consistent with earlier findings in which it was shown that most of reversibly bound IgG aggregates dissociate from the membrane within minutes,[14,16,17] although binding at 4 °C to platelets is essentially complete after a 60-minute incubation period (data not shown).[17] In addition, it cannot be excluded that the binding of aggregates to sites from where they could redistribute at 37 °C is temperature dependent and could be diminished at 4 °C. Nevertheless, both serotonin release and the limited increase of the pronase resistance of associated ^{3}H-BDB-IgG occurred immediately, within five minutes after warming to 37 °C, consistent with a receptor-mediated process in which the binding of the ligand is the rate-limiting step.[23] This obviously was the case in our experiments because incubation of ^{3}H-BDB-IgG with platelets at 37 °C resulted in a maximal increase of pronase-resistant platelet-associated ^{3}H-BDB-IgG at much later stages of the incubation period (Fig 3). Moreover, high amounts of mIgG inhibited both the total association of ^{3}H-BDB-IgG to washed platelets and the pronase-resistant part of it (Fig 5).

Because pronase resistance of ^{3}H-mIgG was not influenced by the presence of BDB-IgG, eg, on activated platelets, receptor clustering through the simultaneous binding of one BDB-IgG molecule to at least two receptors must be envisaged as the triggering mechanism for escape from pronase action. Receptor clustering has been described for lymphocytes,[24,25] whereby two forms are distinguished, the energy-independent patching and the energy-dependent capping that engages the cytoskeleton of the cell. Recently, patching and capping of concanavalin A receptors have also been described on platelets.[26] The capping phenomenon was not dependent on extracellular divalent cations and was inhibited by cytochalasin B, implying that an intact microfilament structure was necessary. Our results obtained with acetylsalicylic acid, prostaglandin E$_1$, and cytochalasin B strongly indicate that the redistribution phenomenon of ^{3}H-BDB-IgG on platelets closely resembles a capping phenomenon. Engulfment of ^{3}H-BDB-IgG was less inhibited by acetylsalicylic acid and prostaglandin E$_1$ than was serotonin release. In contrast to these inhibitors, cytochalasin B, which binds to actin, was able to inhibit engulfment to a greater extent than release of serotonin. We conclude from these results that engulfment of ^{3}H-BDB-IgG depends on a functionally intact cytoskeleton.

Although we have no definitive proof of the site in the platelet to which ^{3}H-BDB-IgG moves to become resistant to pronase digestion, there are strong indications that it is transferred to the open canalicular system. Incubation of platelets pretreated with ^{3}H-BDB-IgG at 37 °C with prostaglandin E$_1$ or deoxyglucose/antimycin A had no or only little effect on pronase resistance, whereas cytochalasin B administrations led to a substantial decrease in pronase-resistant ^{3}H-BDB-IgG (Table 2). This supports the idea that most of the engulfed ^{3}H-BDB-IgG must still be connected to the surface, thus becoming accessible to pronase digestion after disruption of actin filaments. Whether cytochalasin B allows engulfed ^{3}H-BDB-IgG to float back to the surface or whether the opening of the open canalicular system is dilated by the drug cannot be decided from our results. Uptake of proteins into the open canalicular system has been shown by electron microscopy with horseradish peroxidase, cationized ferritin, or ferritin-conjugated wheat germ agglutinin. Peroxidase and cationized ferritin were readily taken up at 37 °C but not at 4 °C,[27] and cationized ferritin or ferritin-conjugated wheat germ agglutinin were taken up at 37 °C into washed platelets but not into washed and fixed platelets.[28,29] Although hardly any pinocytic vesicles were observed,[27] coated pits have been reported.[28,30] Therefore, further processing of engulfed ^{3}H-BDB-IgG is possible, eg, in lysosomes. As yet, we could not demonstrate detectable digestion of ^{3}H-BDB-IgG associated with platelets after two hours at 37 °C, a time long enough to reliably detect digested ligand in phagocytic cells.[31] Whether small amounts of engulfed ^{3}H-BDB-IgG are transferred to storage organelles or whether further engulfment is dependent on extracellular divalent cations needs further investigation.

Partial Characterization of a Binding Site For von Willebrand Factor on Glycocalicin

By Alan D. Michelson, Joseph Loscalzo, Barbara Melnick, Barry S. Coller, and Robert I. Handin

The binding of von Willebrand factor (vWF) to platelet membrane glycoprotein Ib (GpIb) facilitates platelet adhesion to vascular subendothelium. In this study, we provide evidence that the vWF binding site is on glycocalicin (GC), a proteolytic fragment of GpIb, and we examine the role of the carbohydrate portion of GC on that binding. The binding to platelets of 6D1, a monoclonal antibody that recognizes an epitope on GpIb and blocks ristocetin-induced vWF binding to platelets, was inhibited by purified GC. In addition, purified GC inhibited ristocetin-dependent binding of ^{125}I-labeled vWF to platelets. Since GC contains 60% carbohydrate by weight, we assessed the role of carbohydrate sequences on its interaction with antibody 6D1 and vWF. Based on the known sequence of the major oligosaccharide chain of GC—*N*-acetyl neuraminic acid, galactose, *N*-acetyl glucosamine, *N*-acetyl galactosamine—we treated GC sequentially with neuraminidase, β-galactosidase, and β-*N*-acetylglucosaminidase. Removal of sialic acid and galactose residues did not affect GC binding. Removal of *N*-acetyl glucosamine residues did not affect GC binding to 6D1 but did decrease the ability of GC to inhibit vWF binding to platelets, increasing the concentration needed to inhibit binding by 50% (IC_{50}) 40-fold. This suggests that a portion of the oligosaccharide chains on GC contributes to the vWF binding activity of this molecule.

THE VON WILLEBRAND FACTOR (vWF) is a heterogeneous polymeric plasma glycoprotein made up of a series of multimers with estimated molecular masses from 1×10^6 to 20×10^6 daltons.[1] The binding of vWF multimers to platelets facilitates platelet adhesion to vascular subendothelium.[2] Although the stimulus that initiates vWF binding to platelets in vivo is not known, binding can be induced in vitro by incubating platelets with the cationic glycopeptide antibiotic ristocetin.[3] There is considerable evidence that the platelet membrane protein glycoprotein Ib (GpIb) contains one of the binding sites for vWF and that binding to this site is facilitated by ristocetin.[2] There is also evidence that binding of vWF to this site enhances platelet adhesion.[4]

The precise region on GpIb to which vWF binds is unknown, although there is some evidence that it may be localized to a proteolytic fragment of GpIb—glycocalicin (GC). GC has been purified by several laboratories,[5-7] and a monoclonal antibody has been developed that recognizes an epitope on GC, inhibits ristocetin-dependent platelet agglutination, and blocks vWF binding to platelets.[8] In addition, Okumura and Jamieson reported that purified GC inhibited ristocetin-induced platelet agglutination.[9]

Our studies provide additional evidence that the vWF receptor site on GpIb is present on GC and that binding to this site can be studied without the need for detergents to keep GpIb in solution. Although many other cell membrane receptors have been purified and studied in vitro,[10-13] detergents were needed to keep these integral membrane proteins, which are hydrophobic, in solution. It has been possible to study only a few other membrane receptors like the hepatic receptor for IgA[14] and the hepatic asialoglycoprotein receptor[15] in a lipid-free aqueous environment.

These two properties of GC, its solubility in aqueous buffers and its ability to block vWF-dependent platelet reactions, allowed us to quantify vWF binding to GC and to determine some of the structural features of GC that facilitate binding. We have focused on the role of carbohydrate sequences on GC since the molecule is 60% carbohydrate by weight and the sequence of its major oligosaccharide has recently been reported.[16] Although carbohydrate determinants of other receptors may play a role in ligand binding, this functional role can only be inferred from studies on whole cells or partially purified materials. In contrast, with the availability of this purified receptor fragment, we have been able to demonstrate a role for the *N*-acetyl glucosamine residues on GC in the binding of vWF.

MATERIALS AND METHODS

Materials

Polyethylene glycol (PEG), 2-mercaptoethanol (2-ME), iodoacetamide, poly-L-lysine (<M_r>) = 400,000), bovine gamma globulin (Cohn fraction II), bovine albumin (Cohn fraction V), fetuin (type III), and phenylmethylsulfonylfluoride (PMSF) were purchased from Sigma Chemical Co, St Louis. Sodium dodecyl sulfate (SDS) and SDS-PAGE High Molecular Weight Standards were purchased from Bio-Rad Laboratories, Richmond, Va. $Na^{125}I$ and a sheep antimouse immunoglobulin $F(ab')_2$ fragment conjugated with horseradish peroxidase were purchased from New England Nuclear, Boston. Dulbecco's modification of Eagle's medium was purchased from Flow Laboratories, McLean, Va. Ristocetin was purchased from Bio-Data Corp, Horsham, Pa. Iodo-beads were purchased from Pierce Chemical Co, Rockford, Ill. Immulon 1 Plates were purchased from Dynatech Laboratories, Inc, Alexandria, Va. Sephacryl S-1000, Sephadex G-25, Sepharose 6B, and Wheat Germ Lectin-Sepharose 6MB were purchased from Pharmacia Fine Chemicals, Piscataway, NJ. Neuraminidase (1 IU/mL) purified from *Vibrio cholerae*, *N*-2-hydroxyethylpiperazine-*N*-'2-ethanesulfonic acid

(HEPES), *o*-nitrophenyl-β-D-galactopyranoside, and *p*-nitrophenyl-2-acetamido-2-deoxy-α-D-glucopyranoside were purchased from Calbiochem-Behring Corp, La Jolla, Calif. β-galactosidase (1,500 U/mL) purified from *E coli*, β-*N*-acetyl glucosaminidase (20 U/mL), and galactose dehydrogenase were purchased from Boehringer Mannheim, Indianapolis, Ind. Lactoperoxidase, *N*-acetyl neuraminic acid, galactose, *N*-acetyl glucosamine, and *N*-acetyl galactosamine, all of the highest grade available, were purchased from Sigma Chemical Co, St Louis. Trypsin, treated with L-(tosylamido 2-phenyl) ethyl chloromethyl ketone (TPCK) to inhibit contaminant chymotryptic activity, was purchased from Worthington Diagnostic Systems, Inc, Freehold, NJ. Amicon Diaflo Membrane PM30 was purchased from Amicon Corp, Danvers, Mass. *Serratia* protease was a very generous gift of Dr H. Cooper (University of North Carolina, Chapel Hill). All other materials used were of reagent grade or better, and deionized water was used throughout.

Methods

Platelet counting was performed on a Coulter Counter Model F (Coulter Electronics, Hialeah, Fla) Absorbance was measured in a Gilford Spectrophotometer 2400 (Gilford, Oberlin, Ohio), except in the platelet enzyme-linked immunosorbent assay (ELISA) inhibition assay in which a Bio-Tek EIA Reader (Bio-Tek Instruments, Inc, Burlington, Vt) was used. Gamma emission was assayed using a Beckman Model 8000 Gamma Counter (Beckman Instruments, Inc, Fullerton, Calif). Platelet aggregometry was performed on a Payton Dual Channel Aggregometer (Payton Assoc, Inc, Buffalo) and changes in light transmission recorded with an Omniscribe Recorder (Houston Instruments, Austin, Tex).

Fresh platelets. Fresh platelets used in the vWF binding assay were prepared from 20-mL venous blood drawn into 3-mL acid-citrate-dextrose (ACD). After mixing, the sample was centrifuged at 200 g for 10 minutes at room temperature, and only the upper two thirds of the platelet-rich plasma (PRP) was collected to minimize leukocyte and red cell contamination. The pH of the PRP was adjusted to 6.5 by drop-wise addition of ACD and then centrifuged at 3200 g for 10 minutes at room temperature. The platelet pellet was resuspended in 10 mL of 10 mmol/L Tris, 0.15 mol/L NaCl, 20 mM EDTA, pH 7.4, and the centrifugation and washing repeated five times. An additional two washes were performed under the same conditions, except that the platelet pellet was resuspended in 10 mL of 10 mmol/L tris(hydroxymethyl) aminomethane (Tris), 0.15 mol/L NaCl, pH 7.4 (TBS). The platelets were diluted in TBS to a concentration of 5×10^5 per μL for the vWF binding assay.

Formalin-treated platelets. Formalin-treated platelets[17] used in ristocetin agglutination assays were prepared by mixing an equal volume of 2% paraformaldehyde in TBS with freshly prepared PRP in 14 mmol/L sodium citrate and incubating for one hour at 37 °C. Platelets were then either immediately washed or stored at 4 °C for up to 16 hours, after which they were washed twice with 10 mmol/L Tris, 0.15 mol/L NaCl, 20 mmol/L EDTA, pH 7 4, then twice with TBS. Platelets were resuspended at $4 \times 10^5/\mu$L and stored at 4 °C for up to three weeks.

Glycocalicin purification. A modification of the method described by Solum et al[18] was used. Fifty units of outdated platelets (obtained from the American Red Cross Blood Services, Northeast Region, Boston) were pooled and centrifuged at 3,200 g for 30 minutes at 4 °C. The sedimented platelets were resuspended in wash buffer (0.15 mol/L NaCl, 5 mmol/L glucose, 0.6 mmol/L EDTA, 10 mmol/L Tris, pH 7.6) and then centrifuged at 250 g for 15 minutes to remove red cells. The platelets were then washed by centrifuging twice at 3,200 g for 30 minutes, the first resuspension in wash buffer and the second in 320 mL warm (37 °C) 3 mol/L KCl. After the second resuspension, the platelets were incubated for 30 minutes at 37 °C and then centrifuged at 8,000 g for 10 minutes The supernatant (KCl extract) was dialyzed for 18 hours against several changes of buffer A (0.15 mol/L NaCl, 10 mmol/L Tris, 0.6 mmol/L EDTA, 0.01% NaN_3, pH 7.6) and then loaded onto a 10-mL column of Wheat Germ Lectin-Sepharose 6-MB. The column was washed with buffer A until the absorbance at 280 nm returned to baseline levels. The column was then washed with 2.5% *N*-acetyl glucosamine in buffer A, and peak fractions, as determined by absorbance at 280 nm, were pooled and dialyzed against buffer B (1 mol/L NaCl, 10 mmol/L Tris, 0.6 mmol/L EDTA, 0.01% sodium azide, pH 7.6). This fraction was concentrated to 15 mL by ultrafiltration (Amicon Diaflo Membrane PM 30) and applied to a Sepharose 6B column (2.5 × 90 cm). The fractions showing maximal activity in the platelet ELISA inhibition assay were pooled, dialyzed against distilled water, and lyophilized. The yield was approximately 1 mg protein per preparation, as determined by Lowry's method.[19] Before use in assays, GC was reconstituted in TBS, pH 7.4. Incubation of the GC with 0.6 mol/L 2-ME followed by electrophoresis on a 6% polyacrylamide gel in the presence of SDS demonstrated a single band of an approximate molecular weight of 140,000 daltons after staining of the gel with Coomassie blue and periodic-acid Schiff's (PAS) reagent.[20] GC molarity was calculated from its molecular weight and protein concentration, assuming that GC was 60% carbohydrate on a weight basis.[6] GC concentration was also determined by measurement of the absorbance at 280 nm. The specific absorbance of GC at 280 nm was 17.4 based on the protein concentration determined by Lowry's method, with a correction for the carbohydrate content.

vWF purification. Unless otherwise indicated, all steps were performed in polyethylene containers at 25 °C. Two and one-half liters of plasma, prepared from blood collected into citrate-phosphate-dextrose anticoagulant, were obtained within two to three days of collection from the American Red Cross Blood Services, Northeast Region (Boston) and frozen at −30 °C for 24 hours. After thawing at 4 °C for 24 hours, the cryoprecipitate was collected by centrifugation at 5,000 g for 20 minutes. The pellet was resuspended in 20 mmol/L sodium citrate and the pH adjusted to 6.1 with dropwise addition of 20 mmol/L citric acid. Forty percent PEG (wt/vol) ($\langle M_r \rangle = 8{,}000$) was added to give a final concentration of 5% and the resulting precipitate discarded. Additional PEG was added to 12% and the precipitate collected by centrifugation at 5,000 g for 20 minutes. The pellet was gently rinsed once with 10 mL of 50 mmol/L Tris, 0.15 mol/L NaCl, 0.02% NaN_3, 8% ethanol, pH 7.8, and once with 10 mL of 50 mmol/L Tris, 0 15 mol/L NaCl, and 0.02% NaN_3, pH 7.8 (column buffer). The pellet was warmed to 37 °C, dissolved in 10 mL of column buffer and applied to a siliconized glass column containing Sephacryl S-1000 (95 × 2.5 cm) Four milliliter fractions were collected at a 70 mL/h flow rate

Fractions were analyzed for protein concentration and ability to support ristocetin-dependent platelet agglutination.[21,22] Fractions were stored at 4 °C for up to five days without an appreciable loss of ristocetin cofactor (VIII:RCof) activity. The most active fractions, which had activities of approximately 100 units of ristocetin cofactor activity per mg protein (with the activity of pooled plasma being defined as 1 U/mL), were used in all studies. Protein purity of fractions treated with 0.6 mol/L 2-ME was assayed by SDS gels containing 4% polyacrylamide. There was a single 230,000-dalton band in the most active column fractions. Average protein yields were 3 mg/2.5 L plasma vWF was concentrated, when necessary, by ultracentrifugation at 100,000 g for two hours at 4 °C or by dialysis against 20% (wt/vol) PEG ($\langle M_r \rangle = 20{,}000$) at 4 °C.

Native vWF polymer was reduced for 60 minutes at 22 °C with 50 mmol/L 2-ME and alkylated for 15 minutes at 22 °C with 75 mmol/L iodoacetamide. This limited reduction and alkylation resulted in the production of a dimer of vWF[23] that had the same electrophoretic mobility as unreduced fibronectin ($<M_r> \approx 440,000$) when analyzed on 4% polyacrylamide gels in the presence of SDS. In the binding studies presented here, vWF dimer was used because of its uniform size. This avoids the difficulties encountered in quantifying binding with a heterogeneous series of native vWF multimers.

Radioiodination of vWF Two Iodo-beads were incubated with 0.5 to 1 0 mCi of $Na^{125}I$ in 0.1 N NaOH at 25 °C for 10 minutes. To this was added 1.5 mL 0.1 mg/mL vWF in TBS, and the incubation continued for 25 minutes with gentle rocking. The protein solution was then applied to a 10 × 0.7-cm Sephadex G-25 column that had been previously treated with 0.5 mL of 5 mg/mL bovine serum albumin in TBS. Twelve 0.3-mL fractions were collected and assayed for both total and 25% trichloroacetic acid-precipitable radioactivity. Routinely, column fractions 5 to 7 contained a maximal protein-bound activity of approximately 0.1 μCi/μg. These fractions were 80% to 90% precipitable with trichloracetic acid, and they were equivalent to uniodinated vWF on SDS PAGE and in ristocetin cofactor assays.

^{125}I-vWF/platelet binding assay. Inhibition of vWF binding to fresh platelets by GC was measured by a modification of the vWF/platelet–binding assays of Kao et al[3] and Morisato and Gralnick.[24] The following reagents diluted in TBS were mixed at room temperature: 100 μL of 0.1% bovine serum albumin, 50 μL of 10 mg/mL ristocetin, 20 μL of 5×10^5 fresh platelets per μL varying nanomolar concentrations of GC, a final concentration of 0 48 μg/mL unlabeled and ^{125}I-labeled vWF dimer, and sufficient TBS to bring the total assay volume to 500 μL. Parallel assays to determine nonspecific binding were always performed with the identical reagents without ristocetin. After 30 minutes mixing, 200 μL was removed, gently layered onto 500 μL of 50% sucrose, and centrifuged at 8,700 g for four minutes in a Beckman Microfuge. The two fluid layers were separately aspirated with Pasteur pipettes, with approximately 50 μL sucrose and the pelleted platelets left in the tube. The tubes were then assayed for gamma emission. The ristocetin-dependent binding of vWF to platelets was determined by subtracting the calculated value for vWF bound in the assay without ristocetin from the vWF bound in the corresponding assay with ristocetin. The total vWF bound in the presence of ristocetin was typically five times the value without ristocetin. A 100-fold excess of nonradioactive vWF reduced binding of ^{125}I-labeled vWF to the values seen when ristocetin was omitted from the assay. The binding of vWF to platelets was saturable, with 42 ± 2 ng vWF bound per assay (5×10^6 platelets) at saturation. A final concentration of 0.16 μg/mL vWF resulted in 50% binding. The binding of vWF to platelets for a given GC concentration was expressed as a percentage of the binding of vWF to platelets in the absence of GC.

Platelet ELISA inhibition assay. A monolayer of platelets was fixed in plastic microwells by the following method. Fifty milliliters of venous blood was drawn into 7.5 mL of ACD, PRP prepared, and the platelet pellet washed three times as previously described. The platelets were diluted in TBS, 4 mmol/L EDTA, pH 7.4, to a concentration of $10^5/\mu$L. Poly-L-lysine at a concentration of 10 μg/mL was incubated for 30 minutes at room temperature in microwells of flat-bottomed polystyrene plates. The plates were then flicked to remove the poly-L-lysine, and any remaining drops were aspirated. One hundred microliters of the platelet suspension was added to each microwell and the plates centrifuged at 800 g for five minutes. Without removing the buffer, 50 μL of 0.5% formaldehyde (wt/vol) in TBS, 4 mmol/L EDTA, pH 7.4, was added to each microwell, incubated at room temperature for 15 minutes, and the wells washed twice with TBS. Microscopic examination showed that each microwell was covered by a confluent monolayer of platelets with negligible leukocyte or red cell contamination (<1/1,000 platelets). The fixed platelets could be stored without loss of activity for at least 2 months by filling the wells with a 0.1% (wt/vol) solution of bovine albumin in Dulbecco's modification of Eagle's medium with 20 mmol/L HEPES (pH 7.4) and freezing at −20 °C.

A platelet ELISA[25] inhibition assay was developed using a sheep antimouse F(ab')$_2$ fragment conjugated with horseradish peroxidase and a mouse monoclonal antibody (6D1) directed against an epitope on the GC portion of the platelet GpIb.[8] 6D1 was positive to a titer of 1:160 in a screening assay of inhibition of ristocetin agglutination of fixed platelets in microwells, as previously described.[8] 6D1 was purified from ascites by chromatography on protein A–sepharose, and its specific absorbance at 280 nm was 14. A previously prepared Immulon plate was thawed and washed three times with 10 mmol/L Tris and Tween 20, pH 8.0, (washing buffer). Each microwell was filled with bovine gamma globulin solution (5 mg/100 mL TBS) and incubated for 30 minutes at 37 °C. After three washes with washing buffer, 25 μL of varying concentrations of GC in TBS and 25 μL of 175 ng/mL 6D1 were added to each well. After incubation for 60 minutes at 37 °C and three washes with washing buffer, 50 μL of a 1:250 dilution of the F(ab')$_2$ fragment was added to each well. After incubation for 60 minutes at 37 °C and six washes with washing buffer, 50 μL of a 1:1:18 (vol/vol/vol) mixture of 4% *o*-Phenylenediamine, 0.3% H_2O_2, and 17 mmol/L citric acid in 65 mmol/L phosphate, pH 6.3, was added to each well. After incubation for 30 minutes at 37 °C, the color development was stopped by the addition of 50 μL of 4 5 mmol/L H_2SO_4. The optical density (OD) was read at 492 nm and expressed as a percentage of the OD in assays with 6D1 but without GC (100% binding) The OD of assays with neither 6D1 nor GC was defined as 0% binding. Experiments with ^{125}I-labeled platelets demonstrated that the platelet fixed reproducibly to the microwells and remained adherent throughout the assay (1.51 ± 0.06 × 10^6 platelets fixed per well). 6D1 did not bind in assays without fixed platelets.

Radioiodination of platelet surface proteins. Twenty milliliters of venous blood was drawn into 3 ml of ACD, PRP prepared, the platelet pellet washed three times, and iodination carried out as previously described.[26] The platelets were diluted in TBS, 4 mmol/L EDTA, pH 7.4, to a concentration of $1.5 \times 10^9/\mu$L (approximately 1 mL). A 0.25-mCi sample of ^{125}I in 0.1 N NaOH was added, followed by 5 μL of a 1.1 (vol/vol) mixture of lactoperoxidase and TBS, 4 mmol/EDTA, pH 7.4. Ten microliters of 1 mmol/L H_2O_2 was then added every one minute for ten minutes, after which the platelet pellet was washed as previously described, three or four times (depending on the residual amount of gamma emission measured in the supernatant). Platelets were resuspended in TBS after the last wash.

Serratia protease treatment of platelets. Approximately 4 × 10^8 ^{125}I-labeled platelets in 0.5 mL TBS were incubated at 37 °C with *Serratia marcescens* metalloprotease (final enzyme concentration, 10 μg/mL) for time periods ranging from one to 20 minutes.[27,28] The reaction was stopped by adding 10 mmol/L EDTA[27] and centrifuging the samples at 8,700 g for two minutes. Parallel experiments were performed in which the enzyme solution was replaced by TBS only. For each time period of enzyme and control incubations, a sample of both the platelet pellet and the supernatant was run on SDS gels containing 6% polyacrylamide. An autoradiogram was made of the dried gel with x-ray film at −20 °C.

For the platelet ELISA inhibition assay, 4 × 10^8 washed unlabeled platelets in 0.5 mL TBS were incubated at 37 °C for five minutes with *Serratia* protease (final concentration ~ 10 μg/mL) while another 4 × 10^8 washed unlabeled platelets in 0.5 mL TBS were incubated with TBS only. The enzyme reaction was stopped by adding 10 mmol/L EDTA and centrifuging at 8,700 g for two minutes. The control platelets were treated similarly. The platelets were washed three times with TBS, 4 mmol/L EDTA, pH 7.4, and then diluted in that buffer to a concentration of $10^5/\mu$L. Agglutina-

P25710

tion of *Serratia* protease–treated and control platelets by PRP and ristocetin (1 mg/mL) was assessed by the method of Ramsay and Evatt.[29] The treated and control platelets were then fixed in separate microwells of an Immulon 1 polystyrene plate, as described previously.

Exoglycosidase digestions. Lyophilized GC was resuspended in 0.05 mol/L sodium acetate buffer, pH 6, with 1 mmol/L CaCl. This suspension was sequentially incubated with (1) neuraminidase (0.17 U/μg GC protein) for two hours at 37 °C, (2) β-galactosidase (0.20 U/μg GC protein) overnight at 37 °C, and (3) β-*N*-acetylglucosaminidase (0.02 U/μg GC protein) overnight at room temperature. Before use in the binding assay, all exoglycosidase-treated GC was heated to 50 to 56 °C for ten minutes to inactivate the enzymes Using fetuin and measuring released sialic acid,[30] *o*-nitrophenyl-β-D-galactropyranoside,[31] and *p*-nitrophenyl-2-acetamido-2-deoxy-α-D-glycopyranoside,[31] the activities of neuraminidase, β-galactosidase, and β-*N*-acetyl glucosaminidase, respectively, were standardized and the completeness of heat-induced inactivation verified

Carbohydrate analysis. Unbound sialic acid was measured by the Warren method.[30] Total sialic acid of GC and whole platelets was measured after mild acid hydrolysis with 0.1 N H_2SO_4 for one hour at 80 to 82 °C.[32] Galactose was measured by the method of Finch et al.[33] *N*-acetylglucosamine was measured by a modification of the Morgan and Elson color reaction,[34] as described by Levvy and McAllan.[35] A sample of neuraminidase and β-galactosidase-treated GC was hydrolyzed with 3 N HCl for three hours at 100 °C to release *N*-acetylglucosamine.[5] The pH of the sample was readjusted to 6.0 by dropwise addition of NaOH, and then acetic anhydride dissolved in 1.5% acetone (vol/vol) was added to reacetylate the amino group on the sugar.[35]

Gel Electrophoresis Polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate was performed according to the method of Weber and Osborne[36] as modified by Laemmli.[37] The mobility of the vWF dimer was assessed on 4% polyacrylamide gels and compared to unreduced fibronectin. The mobility of native or exoglycosidase-treated ^{125}I-GC and ^{125}I-labeled platelet proteins was assessed on 7.5% polyacrylamide gels. Autoradiography was carried out on dried gels using Kodak XR film exposed for six to 24 hours at −80 °C with intensifying screens.

Protein determination. GC and vWF protein concentrations were estimated according to the method of Lowry and colleagues.[19]

RESULTS

Inhibition of 6D1 binding to platelets by GC and vWF. As shown in Fig 1, increasing concentrations of purified GC progressively inhibited the binding of monoclonal antibody 6D1 to platelets. The concentration of GC needed to inhibit antibody binding by 50% was 12 nmol/L (Fig 1). In contrast, the binding of 6D1 to platelets was not inhibited when 1 μmol/L fetuin, another heavily glycosylated protein, was substituted for GC (data not shown). In addition, GC did not inhibit the binding to platelets of KB 2/1, a monoclonal antibody directed at another protein on the platelet membrane (Fig 1).

Pretreatment of platelets for five minutes with the protease purified from *Serratia marcescens,* which has been reported to selectively remove GpIb from the platelet surface,[27,28] decreased 6D1 antibody binding by 75% and abolished the platelets' ability to be agglutinated by ristocetin in the presence of normal plasma. In contrast, the protease treatment had no effect on the binding of antibody KB 2/1. SDS-PAGE analysis of nonreduced samples of the protease-treated platelets showed complete loss of the GpIb band with the appearance in the supernatant of a new band migrating with an <M$_r$> similar to, or identical with, that of GC.

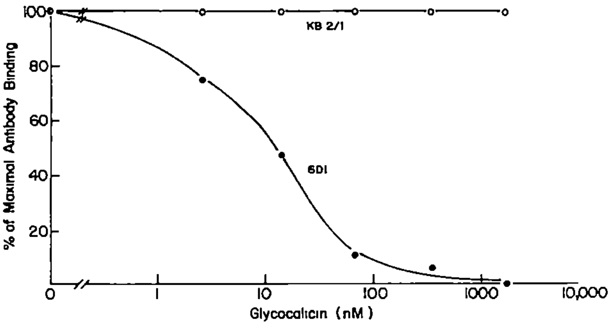

Fig 1. Effect of GC on the binding of two monoclonal antibodies to platelets. Percent binding of antibody to fixed platelets was measured by an ELISA. 6D1 (88 ng/mL) (●) was a monoclonal antibody directed at platelet GpIb. KB 2/1 (○) was a monoclonal antiplatelet membrane antibody that is not directed at GpIb. Each point represents the mean of four experiments (SEM ± 7% to 8%).

The inhibition of 6D1 binding to whole platelets by vWF was then assessed. Binding of 88 ng/mL 6D1 to formalin-treated platelets was not inhibited by simultaneous incubation with up to 43 μg/mL vWF alone. However, the addition of 1.5 mg/mL ristocetin along with 43 μg/mL vWF inhibited 6D1 binding by up to 67%. These studies suggest that the epitope on platelet GpIb and purified GC that is recognized by 6D1 is either located near the binding site for vWF or altered by vWF binding at a site remote from it.

Inhibition of vWF binding to platelets by GC. GC inhibited the ristocetin-dependent binding of the ^{125}I-labeled vWF dimer to the platelet surface (Fig 2). The ^{125}I-vWF dimer bound to platelets in the presence of ristocetin in a saturable and reversible manner and could be inhibited by GC. The IC_{50} for GC using vWF as radioligand was 10 nmol/L (Fig 2). In contrast, vWF binding to platelets was not inhibited when 1 μmol/L fetuin was substituted for GC.

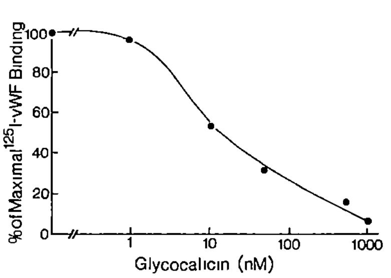

Fig 2. Effect of GC on ristocetin-dependent binding of ^{125}I-vWF to platelets. Binding assay was performed as described in Methods using fresh washed platelets at a concentration of 2 × 10^4/μL, ^{125}I-labeled vWF 0.48 μg/mL, 1 mg/mL ristocetin, and the indicated concentrations of purified GC. Specific binding of vWF was determined by subtracting the results of parallel assays without ristocetin as a measure of nonspecific binding (typically comprising 20% of total binding). Each point represents the mean of three experiments (SEM ± 8% to 9%).

Table 1. Release of Monosaccharides by Combinations of Exoglycosidases

Exoglycosidase Added	Monosaccharide Released (N Moles)*		
	NANA	GAL	*N*-Ac-Glu
Neuraminidase	40.5 ± 5.0	1.2 ± 0.6	3.2 ± 0.4
Neuraminidase and *β*-galactosidase	—	39.5 ± 4.0	3.5 ± 0.5
Neuraminidase, *β*-galactosidase, and *β*-*N*-acetyl glucosaminidase	—	—	10.8 ± 2.0
Acid hydrolysis	44.3 ± 6.0	40.5 ± 4.0	19.5 ± 3.5

Abbreviations: NANA, *N*-acetyl neuraminic acid; GAL, galactose; *N*-Ac-Glu, *N*-acetyl glucosamine.

*Mean ± SEM for four to five separate experiments each done in duplicate.

Effect of exoglycosidase treatment on monosaccharide content and GC-antibody interactions. The ability of native and exoglycosidase-treated GC to inhibit 6D1 antibody binding to platelets was then assessed. Table 1 shows the quantity of monosaccharide released from GC by enzyme incubation. Neuraminidase treatment of GC released 40.5 of a total of 44.3 nmol of sialic acid. Combined neuraminidase and *β*-galactosidase treatment cleaved 39.5 of 40.5 nmol of galactose, and treatment with all three enzymes—neuraminidase, *β*-galactosidase, and *β*-*N*-acetyl glucosaminidase—released 10.8 of a total of 19.5 nmol of *N*-acetyl glucosamine from GC. As shown in the inset to Fig 3, exoglycosidase digestion of GC did not cause significant proteolysis of GC. Several minor bands with $<M_r>$ less then native GC can be seen on the autoradiograms of ^{125}I-GC prior to enzyme treatment. However, the intensity of these bands did not increase after exposure to the exoglycosidases. They represent less than 1% of the total radioactivity. It is interesting, however, that treatment with neuraminidase (lane 2) reduced the mobility of ^{125}I-GC slightly, whereas treatment with additional exoglycosidases (lanes 4 and 5) did not further reduce mobility.

The ability of GC to inhibit 6D1 binding to platelets was not affected by sequential enzyme digestion. Following treatment of GC with neuraminidase alone, neuraminidase and *β*-galactosidase, or the combination of neuraminidase, *β*-galactosidase and *β*-*N*-acetyl glucosaminidase, GC still inhibited 6D1 antibody binding to platelets (Fig 3). In addition, pretreatment of intact platelets with neuraminidase, which removed 49% of the total platelet sialic acid, did not affect subsequent binding of 6D1 to the platelet. Finally, each of the four monosaccharides that make up the carbohydrate sequences on GC[6,16] was substituted for GC in the platelet ELISA assay. None of the four monosaccharides tested—*N*-acetyl neuraminic acid, galactose, *N*-acetyl glucosamine, *N*-acetyl galactosamine—when added over a concentration range of 100 nmol/L to 1 mmol/L, inhibited binding of antibody 6D1.

Effect of exoglycosidase treatment on GC-vWF interactions. In contrast to 6D1 binding, exoglycosidase digestion of GC did modify the interaction of GC and vWF. The ability of GC to inhibit vWF binding to platelets in the presence of ristocetin was not altered by prior treatment of GC with neuraminidase alone nor with the combination of neuraminidase and *β*-galactosidase, as assessed in the ^{125}I-vWF/platelet binding assay (Fig 4). However, sequential treatment of GC with all three enzymes—neuraminidase, *β*-galactosidase, and *β*-*N*-acetyl glucosaminidase—caused a 40-fold increase in the IC_{50} (Fig 4). To be certain that the exoglycosidases present in some of the GC samples did not hydrolyze monosaccharides from the platelet or from vWF and thereby inhibit vWF binding to platelets, we heated enzyme-treated and control GC samples to 50 to 56 °C for

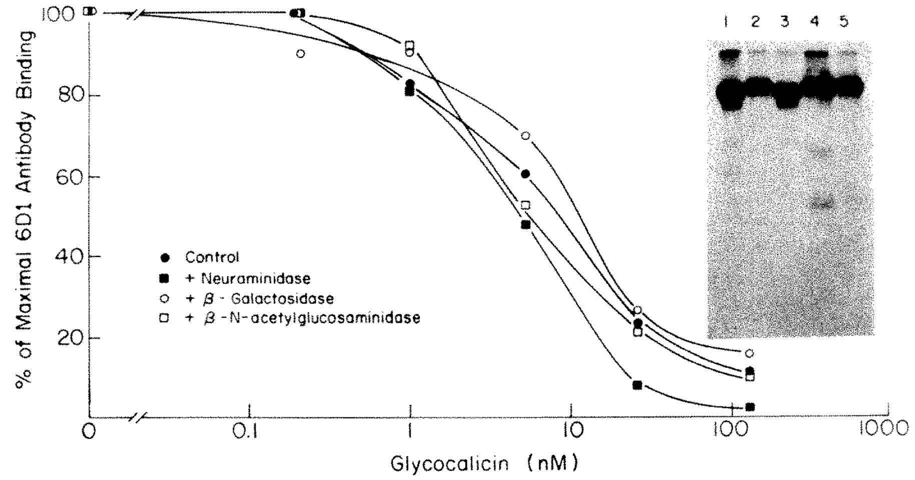

Fig 3. Effect of exoglycosidase-treated GC on the binding of monoclonal antibody 6D1 to platelets. Percent binding of 6D1 (88 ng/mL) to fixed platelets was measured by ELISA. Key: ●, control GC; ■, neuraminidase-treated GC; ○, neuraminidase- and *β*-galactosidase-treated GC; □, neuraminidase-, *β*-galactosidase-, and *β*-*N*-acetyl glucosaminidase-treated GC. The inset depicts an autoradiogram of control and exoglycosidase-treated GC after 5% SDS-PAGE. Lanes 1 and 3, no treatment; lane 2, neuraminidase; lane 4, neuraminidase and *β*-galactosidase; lane 5, neuraminidase, *β*-galactosidase, and *β*-*N*-acetyl glucosaminidase. Each point represents the mean of three experiments (SEM ± 6% to 7%).

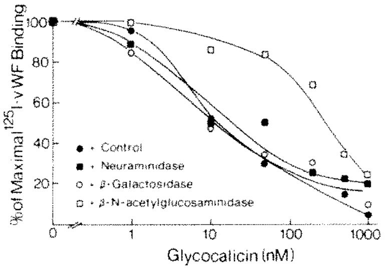

Fig 4. Effect of exoglycosidase-treated GC on ristocetin-dependent binding of ^{125}i-vWF to platelets. Binding assay performed as described in Methods. Reagents: fresh washed platelets, 2 × $10^4/\mu L$; unlabeled and ^{125}I-labeled vWF, 0.48 μg/mL; ristocetin, 1 mg/mL. Key: ●, control GC; ■, neuraminidase-treated GC; ○, neuraminidase- and β-galactosidase-treated GC; □, Neuraminidase-, β-galactosidase-, and β-*N*-acetyl glucosaminidase-treated GC. Each point represents the mean of two experiments.

ten minutes to inactivate the enzymes, which completely inhibited activity of these glycosidases against standard substrates.

DISCUSSION

In this paper, we present evidence that GC, a soluble glycoprotein derived from platelet membrane GpIb, contains a binding site for vWF. First, the binding to platelets of a monoclonal antibody directed at an epitope on GpIb was inhibited (1) both by the ristocetin-dependent binding of vWF, and (2) the addition of purified GC. Second, GC completely inhibited ristocetin-dependent binding of ^{125}I-labeled vWF to the platelet surface.

Other investigators have provided some qualitative evidence that GC contains a platelet vWF receptor of GpIb.[2,7] Platelets from patients with the Bernard-Soulier syndrome completely lack GpIb[38] and do not bind vWF in the presence of ristocetin.[39] Ali-Briggs et al[40] demonstrated that a heterologous polyclonal antibody to GpIb inhibited ristocetin-induced platelet agglutination. Coller et al subsequently developed a monoclonal antibody (6D1) against GpIb that inhibited bovine vWF-induced platelet agglutination.[8] The addition of purified GC reversed this inhibition, suggesting that the antibody was directed at an epitope present on GC as well as GpIb. Okumura and Jamieson[9] previously reported that 1 μmol/L GC inhibited ristocetin-induced agglutination of human platelets by vWF. The data presented here provide further evidence that the binding site for vWF is located on GC and indicate in a quantitative fashion the magnitude of the affinity of GC for this ligand.

In previous studies, Coller[8] determined that monoclonal antibody 6D1 bound to whole platelets with a K_d of approximately 15 nmol/L. Our finding of an IC_{50} of 12 nmol/L for GC inhibition of 6D1 binding to whole platelets suggests that 6D1 antibody binds with equal avidity to GC and GpIb and that the conformation of this epitope is not altered during the cleavage and purification of GC. In contrast, GC inhibited vWF binding to platelets with an IC_{50} of 10 nmol/L, whereas the K_d for the binding to platelets of vWF was 30 nmol/L. This threefold difference may be due to steric effects present on the platelet surface that are mitigated by cleaving GC from that surface.

To determine whether carbohydrate sequences on GC were necessary for wWF binding, GC was incubated with a series of exoglycosidases. Since the sequence of the major oligosaccharide chain of GC has been determined to be *N*-acetyl neuraminic acid, galactose, *N*-acetyl glucosamine, and *N*-acetyl galactosamine,[16] we treated GC sequentially with neuraminidase, β-galactosidase and β-*N*-acetyl glucosaminidase. The results suggest that sialic acid and galactose are not part of the binding site for vWF on the GC portion of GpIb. Partial removal of *N*-acetyl glucosamine residues on GC selectively reduced the binding of vWF, but not 6D1 antibody. Thus, these residues may not be an essential part of the epitope recognized by the 6D1 antibody, but they are required for vWF binding to GC either because they are part of the vWF binding site on GC or because their removal induces a conformational change in the GC molecule. Although the simplest conclusion from these data is that the binding sites for vWF and 6D1 are different (as further supported by the lack of complete inhibition of 6D1 binding to platelets by vWF presented in Results), the possibility remains that the glycosidase treatment results in alterations at an accessory site(s) involved in vWF, but not 6D1, binding and that the major binding sites are, in fact, identical.

Treatment of whole platelets with neuraminidase released 49% of the total platelet sialic acid, a similar percentage to that reported by others.[41-43] The fact that removal of surface sialic acid did not diminish binding of 6D1 antibody to platelets is in accordance with the findings of others as well.[43-45] Neuraminidase treatment of platelets did not diminish their agglutination by ristocetin,[43] their agglutination by bovine factor VIII,[44] or their ability to bind AN51, a monoclonal antibody to GpIb.[45] These experiments are all consistent with the hypothesis that sialic acid is not a part of the platelet vWF receptor on GC/GpIb.

There is evidence that carbohydrate residues on other cell surface proteins may contribute to their biologic activity, such as glycophorin[46] and blood group antigens, ABH and Ii[47] on erythrocytes, the insulin receptor on preadipocytes,[48] and glycoprotein antigens on viruses.[49] Although these whole-cell studies are of great interest, the relationship between carbohydrate modification and receptor activity can only be inferred since many cell surface structures may be modified. This criticism does not apply to the data presented here since purified GC was used as a substrate for exoglycosidases.

Our studies provide an example of carbohydrate-mediated receptor binding that may be unique in several ways. First, GC is a soluble receptor fragment that retains biologic activity after purification and can be studied without lipid cofactors or detergent micelles. Second, it was possible to modify carbohydrate sequences on the purified receptor fragment and then quantify and correlate these modifications with changes in biologic activity. Third, we were able to compare the effect of these carbohydrate modifications on the epitope recognized by a monoclonal antibody with their effect on ligand (ie, vWF) binding. Future studies of this system will be directed towards localizing the vWF binding site to a specific region of the GC molecule and comparing the binding characteristics of soluble and lipid-bound forms of this receptor.

A Diagnostic Test for Heparin-Induced Thrombocytopenia

By David Sheridan, Cedric Carter, and John G. Kelton

Heparin-induced thrombocytopenia can be a serious and difficult-to-diagnose complication of heparin therapy. Serum from patients with heparin-induced thrombocytopenia can cause heparin-dependent platelet aggregation, but the low sensitivity and specificity of this test limit its clinical usefulness. In this report we describe an assay for heparin-induced thrombocytopenia that is both sensitive and specific. The improvement in the assay was accomplished by measuring platelet release instead of aggregation and by measuring platelet release at two heparin concentrations. The rationale for the use of two heparin concentrations was that sera from patients with heparin-induced thrombocytopenia caused release at therapeutic but not at high concentrations of heparin. Twenty-eight sera samples from patients suspected of having heparin-induced thrombocytopenia and 573 controls were coded and tested in the assay. The patients with possible heparin-induced thrombocytopenia were ranked according to the likelihood of having this disorder by using prospectively defined criteria. The test had a high specificity (99%); only one of 573 controls showed a positive result. The test was also very sensitive, and the likelihood of a positive test result was directly correlated with the clinical likelihood of the patient having heparin-induced thrombocytopenia. Six of six patients with definitive heparin-induced thrombocytopenia had positive test results, whereas zero of four patients in whom the diagnosis was unlikely had positive test results. The two-point test for heparin-induced thrombocytopenia represents a sensitive and specific test for this disorder. This test may be useful not only in confirming the diagnosis of this disorder but also may provide information about its pathogenesis.

HEPARIN IS AN EFFECTIVE anticoagulant for the prevention and the treatment of venous thrombosis. Thrombocytopenia develops in approximately 5% to 10% of patients treated with heparin.[1-4] Usually this complication has little clinical impact, but thrombocytopenia in association with arterial thromboses develops in a small proportion of patients treated with heparin.[2] This adverse reaction, unlike isolated heparin-induced thrombocytopenia, results in considerable morbidity, including the occlusion of the arteries supplying the heart, brain, and extremities. In these circumstances it is necessary to discontinue heparin therapy as quickly as possible.[2]

Many of the patients receiving heparin have comorbid conditions that predispose them to thrombocytopenia resulting from other causes, and it can be difficult to be certain of the diagnosis of heparin-induced thrombocytopenia. Yet it is important to be as certain as possible of the diagnosis of heparin-induced thrombocytopenia since discontinuation of the heparin often requires the institution of other antithrombotic therapies such as defibrination or venous ligation that by themselves can result in morbidity. Patients with heparin-induced thrombocytopenia have elevated levels of platelet-associated IgG, but the low specificity of this finding makes a positive result of limited value.[5,6] Previous investigators have demonstrated a heparin-dependent platelet-aggregating factor in sera of patients with heparin-induced thrombocytopenia,[7] and it was suggested that this test could be used to diagnose heparin-induced thrombocytopenia. However, in a prospective study evaluating the usefulness of testing for heparin-dependent platelet aggregation, we found that this response does not occur in every patient.[6] Furthermore, the result of the test is positive in some patients without heparin-induced thrombocytopenia. Problems with both sensitivity and specificity seriously compromise the diagnostic usefulness of any test.

During the performance of our previous study, we made an unexpected observation: sera from patients with heparin-induced thrombocytopenia would initiate platelet aggregation at therapeutic concentrations of heparin, but this response did not occur at high concentrations of heparin. We also observed that ^{14}C-serotonin platelet release was a more sensitive test of platelet activation than was aggregation. These two observations were exploited to develop a sensitive and specific test for confirming the diagnosis of heparin-induced thrombocytopenia.

MATERIALS AND METHODS

Materials. The following materials were used. porcine heparin (Hepalean, Harris Laboratories, Toronto); 5-hydroxy-^{14}C-tryptamine creatinine sulphate (Amersham Corp, Oakville, Canada); calcium- and albumin-free Tyrode's solution containing apyrase, pH 6.2; albumin-free Tyrode's solution, pH 7.4; aqueous counting scintillant (ACS; Amersham Corp)

Sample collection. Serum and plasma samples were obtained from patients in the Hamilton area. The samples from the thrombocytopenic patients receiving heparin were collected within two days of development of the thrombocytopenia. These samples were obtained from subsamples that were collected as part of routine patient management. All samples were heat inactivated for 60 minutes at 56 °C Plasma samples were centrifuged for five minutes at 8,000 g after heat inactivation to remove the fibrin gel, and the supernatant serum was removed. All samples were stored at −70 °C until use

Platelet preparation. Whole blood from healthy individuals was collected into ACD (acid-citrate-dextrose, 1:6, vol:vol) The platelet-rich plasma (PRP) was obtained by centrifugation for 15 minutes at 250 g. The PRP was incubated with ^{14}C-serotonin for 45 minutes at 37 °C (50 μCi ^{14}C-serotonin per mL of PRP) Approximately 50% of

0006-4971/86/6701-0004$03 00/0

the ^{14}C-serotonin bound to the washed platelets, giving a final specific activity of 1.84×10^{-4} μCi of serotonin per 10^6 platelets. The platelets were washed once in calcium- and albumin-free Tyrode's solution and were resuspended in albumin-free Tyrode's solution. The final platelet count was adjusted to 300,000/μL.

Serotonin release assay. Twenty microliters of test serum was mixed with 5 μL of one of two heparin concentrations (0.1 and 100 U/mL, final) and 75 μL of ^{14}C-serotonin–labeled platelets. The platelet mixture was incubated in microtiter wells that contained a magnetic stir bar. Following a 60-minute incubation at 22 °C on a magnetic stir plate set at a slow speed, 100 μL of 0.5% EDTA in saline was added to each well to terminate the release reaction. The platelets were centrifuged for five minutes at 1,500 g, and 50 μL of the supernatant fluid was removed. This aliquot was added to 10 mL of ACS, and the samples were counted in a liquid scintillation counter. The percent release was calculated as follows:

$$\text{percent release} = \frac{\text{release of test sample} - \text{background}}{\text{total radioactivity} - \text{background}} \times 100$$

The background was defined as the supernatant fluid radioactivity from platelets that were handled identically to the test platelets except that buffer was substituted for serum. The total platelet radioactivity was the radioactivity of the test platelet sample. On the basis of preliminary studies, a test result was defined as positive if both of the following criteria were fulfilled greater than 20% release at 0.1 U/mL heparin and less than 20% release at 100 U/mL heparin.

Preliminary studies. Sera from three patients with definite (see subsequent criteria) heparin-induced thrombocytopenia and three normal controls were tested for heparin-dependent ^{14}C-serotonin release. The concentrations of heparin used for these preliminary experiments ranged from 0 to 1,000 U/mL. None of the normal control samples tested induced serotonin release at any of these concentrations, whereas the heparin-induced thrombocytopenia patient samples induced maximum release at therapeutic heparin concentrations (Fig 1).

Patients with possible heparin-induced thrombocytopenia. Sera or plasma from 28 patients with possible heparin-induced thrombocytopenia were available. To categorize these patients, we developed clinical criteria to estimate the likelihood of a particular patient having heparin-induced thrombocytopenia (Table 1). Each patient's hospital record was reviewed by a single individual and the patient classified according to the criteria of Table 1. The patients were then grouped according to their classification, and the results of the assay were compared among groups.

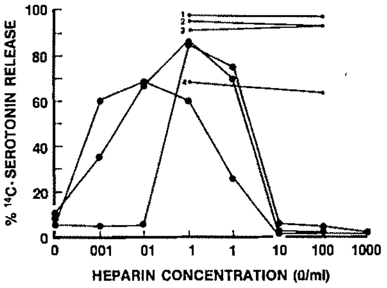

Fig 1. The relationship between the percent release of ^{14}C-serotonin from platelets obtained from healthy individuals (ordinate) and the final concentration of heparin (abscissa). Each series of points is the result obtained with serum from a different patient with definite heparin-induced thrombocytopenia. The lines numbered 1 to 4 represent four different sera samples not from patients with heparin-induced thrombocytopenia. Those samples induced release at 0.1 and 100 U/mL of heparin. Numbers 1 and 2 are sera from two patients with ITP. Number 3 is the serum from a hospitalized control, and number 4 is heat-aggregated IgG.

Table 1. Clinical Criteria for Estimating the Likelihood That a Patient Has Heparin-Induced Thrombocytopenia

- Definite heparin-induced thrombocytopenia
  - Thrombocytopenia develops in patient while receiving heparin, and other causes of thrombocytopenia are excluded. Thrombocytopenia recurs when the patient is rechallenged with heparin, *or*
  - Thrombocytopenia plus acute arterial thrombosis, with other causes of arterial thrombosis excluded.
- Probable heparin-induced thrombocytopenia
  - Thrombocytopenia develops in patient while receiving heparin; *and*
  - Other causes of thrombocytopenia excluded, ie, blood culture is negative; other drugs excluded.
- Possible heparin-induced thrombocytopenia
  - Patient fulfills second criteria, but the thrombocytopenia resolves during continued heparin therapy; *or*
  - Patient fulfills second criteria, but thrombocytopenia does not recur with subsequent administration of heparin (negative rechallenge).
- Heparin-induced thrombocytopenia is unlikely
  - Thrombocytopenia develops in patient while receiving heparin, but another cause for the thrombocytopenia is found; *or*
  - The thrombocytopenia does not resolve after the heparin is discontinued.

Controls The controls consisted of 15 healthy laboratory personnel, 408 unselected hospitalized patients not receiving heparin, 50 hospitalized nonthrombocytopenic patients receiving heparin, and 100 unselected thrombocytopenic patients not receiving heparin. After the test was completed, a positive result was noted in one of the heparin controls, and a review of this individual's chart demonstrated that he had become thrombocytopenic on the day of testing.

Heat-aggregated human IgG served as a positive control for platelet release. Human IgG (Cohn II) was heat aggregated at 63 °C for 20 minutes. This was then incubated with the platelets in place of the serum, and the percent release measured in the usual way.

The patient and control samples were tested at the two heparin concentrations by a single individual who was blinded as to their origin The result was considered positive for heparin-induced thrombocytopenia only if release (greater than 20%) occurred at a heparin concentration of 0.1 U/mL and did not occur at 100 U/mL of heparin.

RESULTS

When attempting to diagnose a relatively uncommon disease, test specificity is of primary importance. The test described in this report was highly specific for heparin-induced thrombocytopenia (Table 1). Only one of 573 control samples showed positive results. The controls included healthy controls (n = 15), nonthrombocytopenic heparin controls (n = 50), hospitalized patients not receiving heparin (n = 408), and patients with thrombocytopenia not resulting from heparin (n = 100). There was only one false-positive result (release at therapeutic concentrations of heparin, 0.1 U/mL, but not at high concentrations of heparin, 100 U/mL). This occurred in a 12-year-old girl with idiopathic thrombocytopenic purpura (ITP) who had never received heparin. One heparin control showed positive test results, but this patient was found to be thrombocytopenic on the day of testing.

The importance of testing for release at high- and low-heparin concentrations is illustrated by the observation that had we defined a positive result only as requiring ^{14}C-serotonin release at a therapeutic heparin concentration (0.1 U/mL), then 21 of the controls would have been misclassified as having heparin-induced thrombocytopenia (Table 2). Many of these patients had ITP, and their sera induced ^{14}C-serotonin release even without the addition of any heparin. These patients clearly represented a group separate from the heparin-induced thrombocytopenia patients since only one of these patients demonstrated inhibition of release at the 100-U/mL concentration of heparin.

The test was sensitive for the detection of heparin-induced thrombocytopenia, and there was a strong relationship between the likelihood of a patient having heparin-induced thrombocytopenia and a positive result in the assay. Six of six patients with definite heparin-induced thrombocytopenia (Table 3) had a positive result, whereas none of the four patients in the fourth group (heparin-induced thrombocytopenia unlikely) and only two of ten in the third group were positive.

The test was positive regardless of whether the patient was receiving heparin at the time of testing or not. Three patients who were classified as having definite heparin-induced thrombocytopenia were receiving heparin at the time the test was performed, and positive results occurred in all. The sera samples from these patients induced platelet release without the addition of heparin, although the addition of 1.0 U/mL of heparin to the test serum did not inhibit the release reaction, as could be predicted from Fig 1.

Platelet release induced by immune complexes (heat-aggregated IgG) was not affected by either concentration of heparin and ranged from 60% to 90% (Fig 1).

The level of platelet-associated IgG was measured at the time of thrombocytopenia in seven of the patients with suspected heparin-induced thrombocytopenia and was elevated in six.

DISCUSSION

Heparin-induced thrombocytopenia is a complication of heparin therapy that can result in morbidity and occasionally death.[1-4] The diagnosis remains one of exclusion because there is no highly sensitive or specific diagnostic test for this disorder.[5,6] Therefore, clinical decisions must be based on diagnostic probabilities. The implications of continuing or discontinuing heparin therapy are considerable, and it would be useful to have a test that could confirm or exclude heparin-induced thrombocytopenia. The in vitro test described in this report represents such a test and is both sensitive and specific for confirming the diagnosis of heparin-induced thrombocytopenia.

Table 2. The Results of the In Vitro Test for Heparin-Induced Thrombocytopenia for 28 Thrombocytopenic Patients Who Were Receiving Heparin

Classification	Number	Number With Positive In Vitro Test Results
Definitive heparin-induced thrombocytopenia	6	6
Probable heparin-induced thrombocytopenia	8	5
Possible heparin-induced thrombocytopenia	10	2
Heparin-induced thrombocytopenia unlikely	4	0

Table 3. Results of Measuring Heparin-Dependent Serotonin Release in the Various Control Populations

Pattern of Serotonin Release	Heparin Concentration (Final)	Number of Various Control Subjects			
		Healthy Controls	Hospital Controls	ITP Patients	Heparin Controls (Nonthrombocytopenic)
<20%	0.1 U	15	395	92	40
<20%	100 U				
>20%	0.1 U	0	13	7	1
>20%	100 U				
>20%*	0.1 U	0	0	1	1†
<20%*	100 U				

*Includes those controls with a positive test (as defined in the text) for heparin-induced thrombocytopenia

†This patient was discovered to be thrombocytopenic at the time of testing.

The technique is based upon two observations: (1) heparin-dependent platelet ^{14}C-serotonin release occurs at therapeutic concentrations of heparin, and (2) very high concentrations of heparin inhibit the release reaction. Others have reported, and we have confirmed, that sera from some patients with heparin-induced thrombocytopenia can induce platelet aggregation in the presence of heparin.[6,7] But, this in vitro test is neither sensitive nor specific.[6] The method described in this report represents an improvement in both sensitivity and specificity. To increase the sensitivity we measured ^{14}C-serotonin release instead of platelet aggregation since immunologic stimuli can induce release without aggregation.[8] The problem with the use of a single concentration of heparin and measuring platelet release as a test for heparin-induced thrombocytopenia is its low specificity. Sera from patients with other thrombocytopenic disorders also can induce platelet release. This difficulty was overcome by assessing the release reaction at two heparin concentrations. Preliminary studies showed that heparin-dependent platelet release was unimodal (Fig 1). Sera from patients with heparin-induced thrombocytopenia caused platelet release at therapeutic concentrations of heparin, but high concentrations of heparin inhibited the reaction. Subsequent studies, not described in this report, have demonstrated that the plasma factor that causes heparin-dependent platelet release is IgG. The unimodal pattern of release may provide insight into the spatial orientation of the binding of the antibody-heparin complex to the platelet. For example, a similar unimodal reaction was observed with malaria-induced thrombocytopenia in which the binding of IgG was directed at platelet-bound antigens.[9] However, unimodal binding also characterizes certain immune complex interactions. Consequently, the characterization of the precise type of binding of IgG-heparin to the platelet surface probably will require the use of immunoglobulin digests.

The inclusion of the high-heparin concentration was the primary factor explaining the increased specificity. Using this test modification, none of the patients that were classified clinically as having definite heparin-induced thrombocytopenia had negative results; however, 20 of 21 control patients whose sera induced release with low concentrations of heparin continued to cause release at high-heparin concentrations. The high specificity of the test for heparin-induced thrombocytopenia was confirmed by testing many other sera samples from patients without this disorder. However, it is more difficult to evaluate test sensitivity because there is not a diagnostic "gold standard" for heparin-induced thrombocytopenia For this reason, we related the in vitro results to a clinical estimate of the likelihood that the patient had heparin-induced thrombocytopenia. We found that those patients with the highest clinical probability of having heparin-induced thrombocytopenia also had the highest positivity rate in the assay. And as the clinical probability of a patient having heparin-induced thrombocytopenia decreased, so did the likelihood of a positive test. It is theoretically possible that other heparin concentrations could be used in the diagnostic test. For example, Fig 1 indicates that a no-heparin-added test in addition to the 0.1-unit test could be as sensitive as the 0.1-unit and the 100-unit test in detecting heparin-induced thrombocytopenia. However, this approach is not always clinically practical since it requires the cessation of heparin therapy to perform the test.

In summary, this study indicates that the measurement of heparin-dependent platelet release at two heparin concentrations can be used as a specific diagnostic test for heparin-induced thrombocytopenia. It is possible that this test also can be used to provide insight into the pathophysiology of heparin-induced thrombocytopenia.

ACKNOWLEDGMENT

The authors wish to thank Drs G. Turpie, P. Powers, M. Ali, and P. Neame for allowing us to study their patients, and Carol Smith who performed many of the release studies.

Biosynthetic (Recombinant) Human Granulocyte-Macrophage Colony-Stimulating Factor: Effect on Normal Bone Marrow and Leukemia Cell Lines

By Masao Tomonaga, David W. Golde, and Judith C. Gasson

To examine the biologic properties of the molecule encoded by the human gene for granulocyte-macrophage colony-stimulating factor (GM-CSF), we expressed the cloned complementary DNA (cDNA) in transfected monkey COS cells and purified the resultant protein. Purified biosynthetic human GM-CSF was added to cultures of normal hematopoietic progenitor cells in semisolid media, and the resulting colonies were characterized cytochemically. Nonadherent light-density bone marrow cells from healthy adult volunteers were maximally stimulated with GM-CSF (approximately 250 pmol/L, and four types of colonies were consistently identified by aspirating the individual colonies and staining with a triple stain for specific and nonspecific esterases and eosinophilic granules. Pure neutrophilic granulocyte (G), mixed granulocyte-macrophage (GM), pure macrophage (M), and pure eosinophil (EO) colonies were observed, the mean incidences on day 8 being 70%, 20%, 5%, and 5%, and on day 14, 7.5%, 16.6%, 50.9%, and 25.0%, respectively. In all types of colonies, complete maturation to segmented forms or typical macrophages was detected. GM-CSF did not enhance the growth of BFU-E from normal peripheral blood buffy coat cells in the simultaneous presence of erythropoietin alone or erythropoietin with purified erythroid-potentiating activity. GM-CSF stimulated HL-60 and KG-1 colony formation twofold and fivefold, respectively; consistent differentiation induction towards monocytic and eosinophilic lineages was observed in HL-60 but not in KG-1. These in vitro findings indicate that GM-CSF is a multilineage stimulator for progenitor cells of G, GM, M, and EO colonies.

COLONY-STIMULATING FACTORS (CSFs) are essential for hematopoietic progenitor cells to proliferate and differentiate in vitro,[1-4] and they likely play an important role in vivo.[5-7] Accurate assessment of the interaction of CSFs with their target cells requires the availability of purified hormone. In this context, murine CSFs have been well characterized, and four distinct molecules are now known to stimulate myeloid progenitors: macrophage CSF (M-CSF) stimulates the growth of macrophage progenitors,[8] granulocyte-macrophage CSF (GM-CSF) acts on both neutrophilic granulocyte and macrophage progenitors,[9] granulocyte CSF (G-CSF) primarily stimulates granulocyte progenitors,[10] and multi-CSF (interleukin 3) has effects on multiple progenitors of erythroid, eosinophilic (EO), megakaryocytic, and mast cell lineages as well as granulocyte and macrophage lineages.[11] Recently, molecular clones encoding murine IL-3[12,13] and GM-CSF[14] have been isolated and characterized.

Human CSFs have been less well characterized. Nicola et al separated two types of CSF from human placental-conditioned medium on the basis of their hydrophobicity[15]: the first activity (CSFα) contains GM-CSF, EO-CSF, and possibly erythroid-CSF[3] activities; and the second one (CSFβ) is very similar to murine G-CSF. Comparable results were reported with conditioned medium from the GCT cell line.[16] We recently purified a 22,000–molecular weight (mol wt) GM-CSF from medium conditioned by the Mo-T-lymphoblast cell line.[17] Complementary DNA clones encoding this human T cell–derived GM-CSF have been isolated, and there is about 60% homology with the nucleotide sequence of the murine GM-CSF cDNA.[18] Purified natural and biosynthetic human GM-CSF have activities on precursor cells, as well as mature neutrophils.[17,19] In this study we define the biologic activity of the purified biosynthetic GM-CSF on human hematopoietic progenitors using in vitro clonal culture of normal blood and bone marrow cells and the human myeloid leukemia cell lines HL-60 and KG-1.

MATERIALS AND METHODS

Cell Preparations

Bone marrow was obtained with informed consent from healthy volunteers by aspiration from iliac crest. Light-density cells were separated by Ficoll-Hypaque density gradient centrifugation. Five million light-density cells suspended in 5 mL of Iscove's modified Eagle's medium (MEM) (Irvine Scientific, Santa Ana, Calif) containing 20% fetal bovine serum (FBS; Hyclone, Logan, Utah) were incubated in a Falcon T-flask (Becton Dickinson, Oxnard, Calif) for two hours at 37 °C in 5% CO_2 in air to deplete adherent cells. Nonadherent light-density cells were gently harvested, washed twice in complete medium, and used for the CFU-GM assay.

For the BFU-E assay, peripheral blood buffy coat cells were treated with Tris-HCL (pH 7.56)-buffered 0.89% ammonium chloride for 9.5 minutes at 37 °C to lyse the contaminating red blood cells The nucleated cells were washed twice with Iscove's MEM containing 10% FBS.

Two human myeloid cell lines, HL-60[20] and KG-1,[21] were used for differentiation-inducing experiments by GM-CSF. Both cell lines have been maintained in Iscove's MEM containing 10% FBS. Cells harvested during exponential growth were used for the experiments

Hematopoietic Stimulators

Purified biosynthetic GM-CSF was obtained from serum-free medium conditioned by COS monkey kidney cells transfected with the GM-CSF cDNA clone in the expression vector p91023 (B).[17,18] The GM-CSF was purified from the conditioned medium by a

modification of the previous method[17] using only gel filtration and reverse-phase high-performance liquid chromatography. The lectin affinity column could be eliminated because of the greater abundance of biosynthetic GM-CSF in the conditioned medium. The purified GM-CSF appeared as a single protein band of 22,000 mol wt on sodium dodecylsulfate polyacrylamide gel electrophoresis, the same molecular weight as the purified natural GM-CSF.[17] The concentration of GM-CSF in a reference preparation was estimated by amino acid analysis; the specific activity of this purified material on normal bone marrow cells is 2×10^8 U/mg. Half maximal activity on bone marrow cells is seen at 10^{-11} mol/L.

Erythroid-potentiating activity (EPA) used in the BFU-E assay was purified from Mo-T cell-conditioned medium as previously reported.[22] Human urinary erythropoietin (EPO) was provided by the Heart, Lung and Blood Institute (Bethesda, Md). The EPO preparation (CAT-1) had a specific activity of 1,140 U/mg protein. The hematopoietic stimulators were serially diluted to various concentrations with Iscove's MEM just before addition to the cultures.

Clonal Culture of Hematopoietic Progenitors in Methylcellulose

Light-density nonadherent bone marrow cells (final concentration, 2.5 to 5×10^4/mL) were plated in Iscove's MEM containing 0.88% methylcellulose, 20% FBS, and GM-CSF at various dilutions in Iscove's MEM. One-half milliliter of semisolid medium was plated in 2.0-cm^2 Falcon well for colony analysis, and 0.1 ml was plated in a Falcon microtiter well for the GM-CSF dose-response studies.

BFU-E assays were performed according to the micromethod previously reported.[22,23] Peripheral blood buffy coat cells (final concentration, 3.3×10^5/mL) were plated in Iscove's MEM containing 0.8% methylcellulose, 20% FBS, 10^{-4} mol/L alpha-thioglycerol, 0.33 U/mL EPO, and 10% volumes of diluted EPA and/or GM-CSF.

CFU-GM colonies were enumerated on day 8 in all cultures and also on day 14 in some, counting cell aggregates containing 20 cells or more as CFU-GM. Erythroid bursts were enumerated on day 14. Well-hemoglobinized colonies containing 100 or more cells were regarded as BFU-E. They were confirmed as having hemoglobin with diaminobenzidine according to Ogawa et al.[24]

Cytochemical Staining of Individual CFU-GM Colonies

After enumerating the number of CFU-GM, individual colonies were aspirated using a finely drawn-out microcapillary tube, carefully avoiding contamination with an adjacent colony or cluster. The aspirated colony was then transferred into a 10-µL droplet of Iscove's MEM placed on a poly-L-lysine-coated glass slide.[25] After complete attachment of colony cells onto the glass surface, medium was removed with absorbent paper and the slides dried rapidly with air. A slide with ten consecutively aspirated colonies was fixed with phosphate-buffered (pH 6.6) formalin-acetone for 30 seconds at 7 °C and subjected to cytochemical staining.

Each slide was triple stained, combining a double stain for specific and nonspecific esterases[26] and an eosinophilic granule stain with Biebrich scarlet[27] to analyze the lineages of the cells composing the colonies. For alpha-naphthyl butyrate esterase (a nonspecific esterase characteristic of the monocyte-macrophage lineage), the slide was covered with a substrate solution containing 1 mg/mL of Fast garnet GBC (Sigma Chemical Co, St Louis) for 15 minutes at room temperature and then washed with distilled water and air dried. For naphthol-ASD chloracetate esterase (a specific esterase characteristic of neutrophilic granulocytes), the slide was covered with a substrate solution containing 0.5 mg/mL of Fast blue RR (Sigma) for 20 minutes at room temperature and washed with distilled water and air dried. For eosinophilic granule stain with Biebrich scarlet (Sigma), the slide was dipped in a 0.1% Biebrich scarlet Tris-HCL (0.1 mol/L, pH 7.2) solution for two hours at room temperature. The slide was washed with distilled water, air dried, and mounted with glycerin gelatin. Using this triple stain, neutrophilic granulocytes from promyelocytes to segmented neutrophils appear as cells with discrete blue cytoplasmic staining (chloroacetate esterase), monocytes and macrophages have diffuse brown cytoplasmic staining (butyrate esterase), and eosinophils appear with coarse red granules (Biebrich scarlet).

In experiments for differentiation induction of leukemic cell lines by GM-CSF, poly-L-lysine-coated slides of pooled colony cells were subjected to the triple stain. In some experiments, single staining with Biebrich scarlet or Luxol fast blue[15,28] was also performed to detect eosinophilic differentiation. The cyanide-resistant myeloperoxidase reaction[26] was used to further confirm enzymatically the eosinophilic nature of Biebrich scarlet- and Luxol fast blue-positive cells.

Clonal Culture of Leukemic Cell Lines in Methylcellulose

HL-60 and KG-1 cells were plated at a final concentration of 3,000/mL and 10,000/mL, respectively, in Iscove's MEM containing 0.92% methylcellulose, 20% FBS, 10^{-4} mol/L alpha-thioglycerol, and 10% diluted GM-CSF. On day 7, colonies consisting of more than 20 cells were enumerated, and the smears of pooled colony cells were made and stained according to the method described previously for CFU-GM colonies.

RESULTS

Response of CFU-GM to Biosynthetic GM-CSF

GM-CSF dose response. Because of our previous results showing that preparations of natural GM-CSF partially purified from Mo-conditioned medium had no activity on mouse or rat bone marrow, all experiments were performed using human peripheral blood and bone marrow cells.[29,30] We determined the relationship of the number of CFU-GM colonies observed to the amount of GM-CSF added to two samples of normal light-density nonadherent bone marrow cells. As seen in Fig 1, the dose-response curve was sigmoid. Further studies using known molar concentrations of the GM-CSF sample (as determined by amino acid analysis) revealed that a 1:1,000 dilution was approximately equal to 250 pmol/L. Stimulation of colony growth was seen at concentrations as low as 2 pmol/L. At submaximal concentrations of GM-CSF, the colony sizes tended to be smaller along with the lower colony numbers. Control cultures without GM-CSF did not show any colony formation.

Cytochemical analysis of individual CFU-GM colonies. Colonies that developed at maximal stimulation with GM-CSF were analyzed using five separate bone marrow samples. The colonies were classified into four subtypes: pure neutrophilic granulocyte (G) colonies showing only chloroacetate esterase-positive cells, mixed granulocyte-macrophage (GM) colonies with a mixture of chloroacetate esterase-positive cells and butyrate esterase-positive cells, pure macrophage (M) colonies with only butyrate esterase-positive cells, and pure eosinophil (EO) colonies with only Biebrich scarlet-positive cells. In general, the sizes of the individual colonies varied from 20 to more than 300 cells.

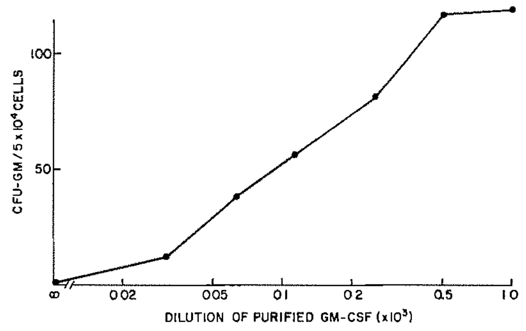

Fig 1. Biosynthetic GM-CSF dose response by normal human CFU-GM. Each point represents the mean value of two normal bone marrow samples. For each sample, triplicate cultures were performed at each dilution of GM-CSF. A 1:1,000 dilution of GM-CSF in this experiment was approximately equivalent to 250 pmol/L.

GM and M colonies tended to be larger than G and EO colonies. No unstained colonies were found. To obtain the distribution pattern of these cytochemically defined subtypes of colonies in each sample, 76 to 117 colonies were randomly aspirated and stained. Day 8 colonies were analyzed in all samples, and day 14 colonies in two samples. To avoid the development of fusion colonies, the number of light-density bone marrow cells plated was reduced to as low as 2.5×10^4/mL. This concentration usually yielded about 20 colonies per well. As shown in Table 1, the mean number of CFU-GM colonies formed was $102/5 \times 10^4$ cells. The four subtypes of colonies were consistently observed in all samples. G colonies predominated (70%) in all samples. GM colonies comprised 20%, and M and EO colonies about 5%.

The G colonies consisted of granulocytes of various maturational stages: promyelocytes and myelocytes being predominant, but band and segmented forms were consistently observed. Chloroacetate esterase–negative cells, indicative of immature blast cells, were not observed. GM colonies consisted of two types: one with a minor population of granulocytes among predominant monocytes-macrophages, and the other with almost equal numbers of cells of the two lineages. GM colonies with monocytes-macrophages as a minor population were rarely observed. The M colonies were usually composed of monocytes with moderate butyrate esterase activity, large macrophages with marked butyrate esterase activity, and intermediate cells showing maturational transition.[31] Rare M colonies, however, showed a pure population of monocytes that contained a few butyrate esterase–negative cells, probably representing immature monocytes such as monoblasts or promonocytes.[31]

The EO colonies showed substantial variability in frequency among the five samples. The lowest value of 0.9% observed in sample 5, however, increased to 12% in the day 14 analysis. The EO colonies usually consisted of 20 to 40 cells; mononuclear cells predominated, but a few bilobed forms also developed.

Two samples analyzed on day 14 exhibited a similar tendency in that the percentages of M and/or EO colonies became higher compared with those on day 8. Control culture without GM-CSF never yielded distinct colonies consisting of more than 20 cells in any sample.

Response of HL-60 and KG-1 Cell Lines to Biosynthetic GM-CSF

Although in control CFU-GM assays no detectable colonies were formed, the possibility remains that accessory cells such as a small number of phagocytic cells and lymphocytes in the light-density nonadherent bone marrow cell samples played some role in giving rise to colonies in GM-CSF–containing cultures.[32] This consideration led us to use HL-60 and KG-1 as homogeneous target cells. HL-60 may be induced to differentiate toward mature granulocytes and/or monocytes-macrophages by various compounds such as dimethyl sulfoxide, retinoic acid, tetradecanoyl phorbol ester, chemotherapeutic agents, and crude and purified lymphokines.[33-41] The KG-1 cell line is also known to be inducible toward macrophage differentiation by phorbol diesters and vitamin D derivatives.[40,41]

In HL-60, the liquid culture sample and unstimulated colony culture cells showed almost the same pattern of enzymatic expression: chloroacetate esterase–positive cells predominated and butyrate esterase–positive cells were negligible in number. However, a small proportion of cells was found to stain weakly with Biebrich scarlet stain. In stimulated cultures, the number of Biebrich scarlet–positive cells was consistently increased with increasing concentrations of GM-CSF (Table 2). The number of butyrate esterase–positive cells also increased. In contrast to the marked change in

‡GM-CSF was added to give a final dilution of 1:1,000 (Fig 1).

Each culture was performed in triplicate. Colony number is the mean ± SEM For cytochemical analysis of pooled colony cells, 300 cells were examined on a triple-stained smear, and the positive rate for each reaction was calculated

HL-60, KG-1 did not show a change in enzymatic pattern, and Biebrich scarlet–positive cells never appeared (Table 2).

To confirm the eosinophilic nature of the Biebrich scarlet–positive cells in the HL-60 cell line, Luxol fast blue and Wright-Giemsa staining was performed Distinct Luxol fast blue positivity and eosinophilic stain with Wright-Giemsa were recognized in almost the same percentages as with Biebrich scarlet stain. The percentage of cyanide-resistant peroxidase-positive cells in HL-60 cells stimulated with GM-CSF was also equal to that of Biebrich scarlet– and Luxol fast blue–positive cells.

Response of BFU-E to Biosynthetic GM-CSF

The effect of GM-CSF on erythroid burst formation was examined in cultures containing low concentrations (0.33 U/mL) of EPO (Fig 2). No enhancement of erythroid bursts was seen in cultures containing amounts of GM-CSF shown to be stimulatory on CFU-GM (Fig 2B). This observation is in contrast to the consistent burst formation in the standard EPA- and EPO-containing cultures (Fig 2A). The addition of GM-CSF to the standard EPA- and EPO-containing cultures did not enhance BFU-E numbers, but rather caused a measurable decrease in cloning efficiency (Fig 2C).

DISCUSSION

Purified biosynthetic (recombinant) GM-CSF produced by COS monkey kidney cells transfected with a cDNA clone–encoding human GM-CSF caused consistent stimulation of normal CFU-GM proliferation and differentiation. The GM-CSF dose-response curve was typically sigmoid, and in several experiments we have seen no inhibitory effect at concentrations up to 1 nmol/L. All of the three G, GM, and M colony types were stimulated, as well as eosinophil colonies. G colonies predominated in day 8 cultures, most becoming diffuse and losing colony configuration by day 14. In contrast, M and EO and some of the GM colonies continued their growth to reach larger-colony sizes during the second week of incubation. The resultant colony number was considerably decreased on day 14. This difference in the rate of colony formation may reflect the kinetic characteristics of each CFU-GM subpopulation in response to GM-CSF. It remains to be seen whether the GM-CSF can stimulate all CFU-GM or a specific subset. Theoretically, purification of all human CSFs is a prerequisite for such a study.

The presence in the light-density nonadherent bone marrow cell sample of accessory cells capable of releasing CSFs[30] makes it difficult to draw unambiguously the conclusion that GM-CSF has direct activities on CFU-GM and CFU-EO. An ideal experimental system would require single cells capable of differentiation to granulocytes/macrophages and eosinophils in the presence of pure CSF. To examine the direct actions of GM-CSF, we chose human myeloid leukemia cell lines as readily available homogeneous target cells for GM-CSF. Both HL-60 and KG-1 responded to GM-CSF by increasing their proliferative rates in liquid culture (data not shown) and plating efficiencies in methylcellulose culture.

Cytochemical examination of GM-CSF–stimulated HL-60 cells and KG-1 cells showed that HL-60 can be induced to differentiate towards monocytic and eosinophilic lineages. Some of the stimulated HL-60 cells became fully mature eosinophils or macrophages. Eosinophilic granules stained with Biebrich scarlet or Luxol fast blue were also positive for cyanide-resistant peroxidase, confirming the eosinophilic nature of these HL-60 cells. As the unstimulated cultures of HL-60 contained small proportions of Biebrich scarlet–positive cells, the stem cells of this cell line appear to have a multipotential ability to differentiate toward monocytic and eosinophilic as well as neutrophilic lineages when properly stimulated. Induced differentiation of the HL-60 cell line has been extensively investigated;[33–41] however, there are only a few published analyses of eosinophilic differentiation.[42–44] Lu et al observed an increase of eosinophilic colonies after 14 days of methylcellulose culture stimulated by crude sources of CSF.[42] In contrast, Metcalf did not note such an increase in agar culture stimulated by GM-CSFα.[43] In the present study, the total increase in the number of eosinophilic cells and the appearance of more mature forms with confluent large granules were apparent. In contrast to HL-60, the enhanced proliferation of the KG-1 cell line by GM-CSF was not accompanied by differentiation induction. The consistent differentiation induction of HL-60 by GM-CSF toward monocytic and eosinophilic lineages is compatible with the findings obtained in the CFU-GM assay of normal hematopoietic progenitor cells.

In the present study, we were unable to detect basophilic colonies from normal bone marrow samples or basophilic differentiation in GM-CSF–stimulated HL-60 cells. We stained 100 colonies from sample 4 and pooled HL-60 colony cells with toluidine blue No colony nor HL-60 cells showed a distinct metachromasia for this dye, suggesting that basophil stimulation is not a functional activity of the GM-CSF. However, there still remains a possibility that CFU-Baso was present at a rate lower than 1% of the CFU-GM colonies and missed from the present aspiration analysis.

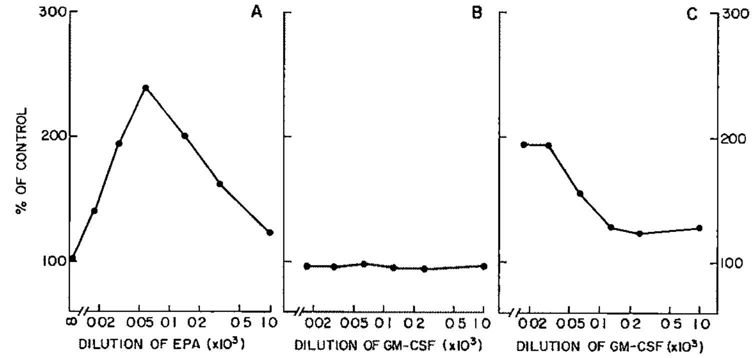

Fig 2. Response to biosynthetic GM-CSF by normal human BFU-E. (A) EPA dose response of BFU-E at an EPO concentration of 0.33 U/mL. (B) GM-CSF dose response of BFU-E in a culture containing EPO (0.33 U/mL) only. (C) GM-CSF dose response of BFU-E in a culture containing EPA (× 16,000 dilution:peak stimulation in Panel A) and EPO (0.33 U/mL). The mean number of BFU-E obtained in the control cultures (from two different donors) with only EPO (0.33 U/mL) were 17 and 55 per well (3.3 × 10^4 cells in 0.1 mL). These values were defined as 100% in each experiment. Each point represents the mean value of two normal peripheral blood buffy coat samples assayed in duplicate. A 1:1,000 dilution of GM-CSF in these experiments was approximately equivalent to 250 pmol/L.

It has been reported that purified murine GM-CSF is capable of stimulating BFU-E. Metcalf et al showed by the sequential addition of purified GM-CSF, a burst-promoting activity (BPA) and EPO in a single hematopoietic progenitor cell culture assay, that the GM-CSF can stimulate the initial divisions of BFU-E, although it did not induce terminal maturation of BFU-E leading to EPO responsiveness.[45] Our observations using simultaneous addition of human biosynthetic GM-CSF to BFU-E assays containing EPA and EPO or EPO alone did not result in stimulation of BFU-E Since the addition of large amounts of GM-CSF to the EPO plus EPA assay caused a detectable inhibition of burst formation, some unidentifiable interactions between these stimulators and progenitor or accessory cells are suggested. In this context, others using the same recombinant GM-CSF sample observed a consistent stimulatory activity on BFU-E growth (David Nathan and Colin Sieff, Dana-Farber Cancer Institute, Harvard Medical Society, personal communication, July 1985). Further experiments are required to elucidate the interactions of EPA, EPO, and GM-CSF on human BFU-E. Human GM-CSF also differs from murine multi-CSF (IL-3), which exerts stimulatory activity on multiple progenitors of erythroid,[46] megakaryocyte,[47] eosinophil,[47] and mast cell[48] lineages as well as on granulocyte and monocyte lineages.

It is apparent that comparative studies on the biologic differences between human GM-CSF and other CSFs purified to homogeneity from various sources are needed. Such comparisons, along with genetic structure analyses, will clarify how many kinds of human CSF exist and their biologic roles in the control of human hematopoiesis. Based on the present observations, we can conclude that T cell-derived human GM-CSF is stimulatory to CFU-GM and CFU-EO

NOTE ADDED IN PROOF

Biosynthetic GM-CSF stimulated the growth of human BFU-E in the presence of erythropoietin when the precursor cells were enriched by removing adherent, phagocytic, and E-rosetting cells from the buffy coat.

Biologic Properties In Vitro of a Recombinant Human Granulocyte-Macrophage Colony-Stimulating Factor

By D. Metcalf, C.G. Begley, G.R. Johnson, N.A. Nicola, M.A. Vadas, A.F. Lopez, D.J. Williamson, G.G. Wong, S.C. Clark, and E.A. Wang

Recombinant human granulocyte-macrophage colony-stimulating factor (rH GM-CSF) was purified to homogeneity from medium conditioned by COS cells transfected with a cloned human GM-CSF cDNA and shown to be an effective proliferative stimulus in human marrow cultures for GM and eosinophil colony formation. The specific activity of purified rH GM-CSF in human marrow cultures was calculated to be at least 4 × 10^7 U/mg protein. Clone transfer experiments showed that this proliferation was due to direct stimulation of responding clonogenic cells. Acting alone, rH GM-CSF did not stimulate erythroid colony formation, but in combination with erythropoietin, increased erythroid and multipotential colony formation in cultures of peripheral blood cells. rH GM-CSF had no proliferative effects on adult or fetal murine hematopoietic cells, did not induce differentiation in murine myelomonocytic WEHI-3B cells, and was unable to stimulate the survival or proliferation of murine hematopoietic cell lines dependent on murine multi-CSF (IL 3). rH GM-CSF stimulated antibody-dependent cytolysis of tumor cells by both mature human neutrophils and eosinophils and increased eosinophil autofluorescence and phagocytosis by neutrophils. From a comparison of these effects with those of semipurified preparations of human CSFα and -β, it was concluded that rH GM-CSF exhibited all the biologic activities previously noted for CSFα.

THE granulocyte-macrophage colony-stimulating factors (CSFs) are specific glycoproteins that control the production and functional activity of granulocytes and macrophages. Four murine CSFs[1] and one human-active GM-CSF[2,3] have been purified to homogeneity and some of their biologic actions determined. Complementary DNAs (cDNA) for two murine CSFs (GM-CSF[4] and Multi-CSF[5,6] [IL-3]) have been cloned and the biologic activity of their translation products in monkey COS cells shown to be identical to that of the corresponding CSFs purified from murine sources.[7-9]

Recently, a cDNA for a human-active GM-CSF has been cloned from a library prepared from the human Mo T-leukemia cell line, and analysis showed a 70% homology in the nucleotide sequence of the protein-coding region with murine GM-CSF cDNA.[2] GM-CSF with the same *N*-terminal amino acid sequence was independently purified from Mo-conditioned medium[2,3] and shown to stimulate granulocyte-macrophage colony formation by human cells. Both native and recombinant GM-CSFs were also shown to be active on mature human polymorphs, inhibiting their migration [2,10]

Previous biochemical studies have indicated the presence of at least two distinct forms of CSF able to stimulate granulocyte and macrophage colony formation by human cells in media conditioned by normal human placenta,[11] the human GCT tumor cell line,[12] and the U5637 bladder cancer cell line.[13] These have been termed CSFα and CSFβ[11] and have been shown to differ in their range of progenitor target cells. Preparations containing CSFα have been observed to stimulate eosinophil colony formation, but preparations containing CSFβ do not.[11] Human CSFα is inactive on mouse cells, but CSFβ resembles murine G-CSF biochemically, is a good proliferative stimulus for murine granulopoietic cells, is able to induce differentiation in murine myeloid leukemia cells, and competes with murine G-CSF for receptors on both murine and human cells.[13]

These studies were undertaken to determine whether the present human GM-CSF cDNA codes for the production of a GM-CSF of an α or β type or a novel type of CSF with other properties. CSF was produced by transfection of monkey COS cells with the human GM-CSF cDNA, and the CSF secreted by these cells was purified by separative protein chemistry. A series of assays was performed using this purified recombinant CSF to determine its range of functional activities.

MATERIALS AND METHODS

Preparation and Purification of rH GM-CSF

The cDNA for human GM-CSF was cloned from a cDNA library constructed using messenger RNA (mRNA) from the Mo human T-leukemia cell line by screening candidate clones in a direct expression system using COS cells To prepare rH GM-CSF for testing, mass cultures of COS cells in cell factories (Nunc, Roskilde, Denmark) were transfected with cloned human GM-CSF cDNA in the p 91203 (B) vector. The final medium fed to the cells was serum free, and after four days of further incubation the medium was harvested, concentrated by ultrafiltration, and the GM-CSF purified to homogeneity as previously described.[2,3] Sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoretic analysis of the purified GM-CSF revealed a major silver-staining band of 19 kilodaltons (kD) with several very faint bands in the 16 to 19 kD range. From bovine serum albumin (BSA) standards, the protein content of the purified material prepared for biologic testing was estimated to be 20 μg/mL.

Assays on Recombinant Human GM-CSF

The purified recombinant human GM-CSF preparation (rH GM-CSF) was diluted 1:100 in 10% fetal calf serum (FCS)-saline, and serial dilutions of 0.1 mL were added to the cultures for assay

Human marrow cultures. Marrow and peripheral blood samples were obtained with the prior informed consent of patients according to a protocol approved by the Ethics Committee of the Walter and Eliza Hall Institute. Fifty thousand unfractionated human bone marrow cells from patients with no significant hematologic disease were cultured in 35-mm Petri dishes using 1 mL of Dulbecco's modified Eagle's medium and a final concentration of 20% FCS and 0.3% agar. Cultures were incubated for up to 14 days at 37 °C in a fully humidified atmosphere of 10% CO_2 in air.

Colony formation (clones of more than 40 cells) was scored at ×35 magnifications using a dissection microscope after seven and 14 days of incubation. To determine the cellular composition of the resulting colonies, whole cultures were fixed using 2.5% glutaraldehyde and methanol and, after drying, stained with Luxol fast blue/hematoxylin. Colony classification was performed at ×400 magnifications.

Units of colony-stimulating activity were calculated from the linear portion of the dose-response curve assigning 50 U/mL to the concentration stimulating the formation of 50% of the maximal colony numbers.

The human placental–conditioned medium (HPCM) stage II used in these experiments was prepared as described previously.[11] The semipurified CSFα and -β fractions were obtained using phenyl-Sepharose chromatography of medium conditioned by the human bladder cancer cell line U5637, using methods described previously.[11]

Human peripheral blood cultures A total of 2×10^5 nonadherent peripheral blood cells from β-thalassemia patients were cultured in agar medium with or without the addition of 1.5 units of semipurified human urinary erythropoietin using Iscove's modified Dulbecco's medium and 25% FCS. Cultures were scored after 14 days of incubation and, after fixation, stained with benzidine/hematoxylin for colony classification.

Murine assays. Volumes of 0.1 mL of serial dilutions of rH GM-CSF were added to agar cultures of 75,000 C57BL adult marrow cells in 20% FCS or 20,000 12-day CBA fetal liver cells in 20% human plasma. Control cultures contained 400 units of purified murine GM-CSF, Multi-CSF, G-CSF, M-CSF,[1] or saline. Colony formation was scored after seven days of incubation. To determine whether rH GM-CSF could initiate but not sustain colony formation by murine hematopoietic cells, 400 units of Multi-CSF were added after two days of incubation to replicate cultures of fetal liver cells, and the cultures were scored after a total incubation period of seven days. After scoring, cultures were stained with Luxol fast blue/hematoxylin and colonies classified according to cellular composition.

Microwell assays using the continuous hematopoietic cell lines 32D cl.3 (kindly supplied by Dr J. Greenberger, Harvard Medical School, Boston) and FCD-P1 (kindly supplied by Dr T.M. Dexter, Paterson Laboratories, Manchester) were performed in microtiter trays using 200 cells per well in 10 μL of Dulbecco's modified Eagle's medium with 20% FCS. Serial dilutions of 5 μL of each test sample were added and viable cell counts performed after 48 hours of incubation.

To determine whether rH GM-CSF was able to induce differentiation in WEHI-3B D^+ myelomonocytic leukemic colonies, 0.1 mL of serial dilutions of rH GM-CSF were added to agar cultures of 300 WEHI-3B D^+ cells. The percentage of colonies exhibiting differentiation was determined after seven days of incubation.[14] Control cultures contained 0.1 mL of serial dilutions of serum from C57BL mice injected three hours previously with 5 μg of endotoxin that contained G-CSF or semipurified human CSFα and -β.

Clone Transfers

Sequential clones developing in marrow or peripheral blood cultures after four to eight days of stimulation by rH GM-CSF were removed intact using a fine Pasteur pipette of a small enough diameter to ensure a minimal amount of surrounding agar and no contaminating cells in the surrounding agar

Clones were placed on the surface of recipient agar cultures containing no cells but either 0.1 mL saline, 0.1 mL rH GM-CSF, 0.1 mL HPCM, or for peripheral blood clones, 1.5 units of erythropoietin or 1.5 units of erythropoietin plus 0.1 mL rH GM-CSF. The concentrations of rH GM-CSF and HPCM used in the recipient cultures were 200 or 400 U/mL. Five clones were transferred to each recipient culture, a procedure ensuring a subsequent 1:500-fold dilution of any stimulus carried over in the agar droplets surrounding the clone.[15] The cell content of the clones was recorded immediately after transfer. After a further six to ten days of incubation, the size of transferred clones was again recorded and the clones placed on microscope slides and stained either with Luxol fast blue/hematoxylin or benzidine/hematoxylin.[1]

Functional Activation of Mature Cells

Mature neutrophils and eosinophils were fractionated from normal human peripheral blood using a hypertonic metrizamide gradient as described previously.[16]

Antibody-dependent cytolysis of tumor cells. These assays were performed using rabbit IgG antidinitrophenyl (anti-DNP) antibodies and tripitrophenyl (TNP)-coupled mouse P815 mastocytoma cells as described previously.[17] The incubation time used was 2.5 hours.

Autofluorescence of eosinophils. After an incubation period of one hour, autofluorescence of eosinophils was monitored by fluorescence-activated cell sorting (FACS) analysis at 460 nm as described previously.[18]

Phagocytosis. Human peripheral blood neutrophils, prepared as previously mentioned, were suspended at 20×10^6 cells per mL in phosphate-buffered saline (PBS). Dried bakers' yeast (Tandaco, Melbourne) was suspended in PBS so that optical density (OD) 540 equaled 1.6

The rH GM-CSF in medium/FCS was diluted in buffer (8.0 g NaCl, 0 2 g KCl, 1 15 g Na_2HPO_4, 0.2 g $MgCl_2 \cdot 6H_20$, 0.11 g $CaCl_2$, and 0.4 g glucose per liter of distilled water, pH 7.4). The final concentration of the rH GM-CSF in the assay was 2 ng/mL.

Assays were performed in triplicate in Wasserman tubes kept at 4 °C until the addition of the following CSF in buffer, 50 μL; yeast, 250 μL; fresh autologous serum, 100 μL; and cells, 100 μL Tubes were incubated for one hour at 37 °C, placed on ice, centrifuged at 4 °C, and then the cells were resuspended in 50 μL cold PBS. Smears were prepared, fixed in methanol, and stained with Giemsa. At least 200 cells were scored per preparation, counting the number of phagocytosed yeast organisms. Total counts were pooled for the triplicate CSF and buffer control preparations, compared by χ^2 analysis, and expressed as percentages.

Binding Competition Assays

The preparation of radioiodinated G-CSF and the binding assay to WEHI-3B D^+ cells have been described in detail elsewhere.[13] Briefly, 1×10^6 WEHI-3B D^+ in 120 μL of Dulbecco's modified Eagle's medium containing 10% (vol/vol) FCS were incubated with 150,000 cpm of ^{125}I G-CSF with or without a 20-fold excess of unlabeled G-CSF or varying concentrations of the test competitor at 37 °C for one hour. Cell-bound radioactivity was separated from unbound radioactivity by centrifugation of cells through FCS and cell pellets counted on a LKB Autogamma gamma counter (Uppsala, Sweden).

RESULTS

Colony Formation Stimulated by rH GM-CSF in Cultures of Human Marrow Cells

To minimize the risk of missing direct or indirect effects of rH GM-CSF, initial assays were performed using serial dilutions of purified recombinant material in unfractionated cultures of 50,000 bone marrow cells from patients without significant hematologic disease. Control cultures were stimulated by unfractionated human placental–conditioned medium or semipurified fractions of CSFα and -β. The recombinant material exhibited colony-stimulating activity in agar cultures of all 14 marrow samples tested, and a typical example of the results obtained is shown in Fig 1. From this titration curve it was calculated that the colony-stimulating activity of the rH GM-CSF preparation was 4 × 10^7 U/mg. In the example shown in Fig 1, the recombinant material stimulated plateau numbers of both day 7 and day 14 colonies at a concentration of 5 ng/mL, and with progressive reduction of this concentration, a typical sigmoid dose-response curve was obtained, the lowest concentration stimulating detectable colony formation being approximately 300 pg/mL. With the 14 marrow samples analyzed in detail, individual marrows varied up to fourfold in their responsiveness to stimulation by the recombinant material, and with some marrow samples, maximal colony formation was observed with a concentration of 1 ng/mL, giving an estimate of specific activity of 1.6 × 10^8 U/mg.

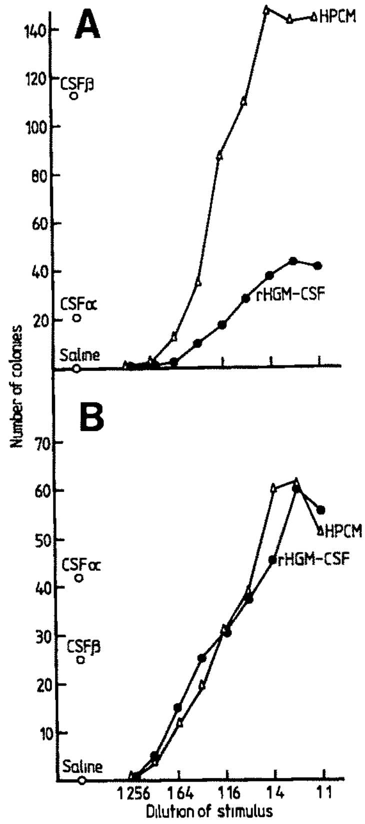

Fig 1. Colony formation at days 7 (A) and 14 (B) in cultures of 50,000 human marrow cells stimulated by 0.1 mL of serial dilutions of a preparation containing 200 ng/mL purified rH GM-CSF. Control cultures contained 0.1 mL of serial dilutions of stage II HPCM or semipurified preparations of CSFα and CSFβ. Note the rise with time in the number of colonies in cultures stimulated by rH GM-CSF.

For the 14 marrow samples analyzed, colony counts at seven days with the various stimuli were as follows: rH GM-CSF 41 ± 30; HPCM, 140 ± 110; CSFα, 27 ± 34; and CSFβ, 138 ± 77 (±SD). At 14 days the following counts were recorded: rH GM-CSF, 85 ± 55; HPCM, 103 ± 96; CSFα, 54 ± 40; and CSFβ, 37 ± 35 (±SD). It will be seen that using rH GM-CSF colony counts rose between seven and 14 days, a characteristic of CSFα but not CSFβ, and individual examples of these trends are shown in Fig 1 and Table 1. A characteristic feature of the cultures stimulated by rH GM-CSF was the relatively slow onset of the development of colonies, a feature also seen in cultures stimulated by CSFα-containing preparations and contrasting with the early onset and early disappearance of colony formation in cultures stimulated by CSFβ.[19]

As shown in the example in Fig 1, the number of colonies stimulated by rH GM-CSF was usually lower than that stimulated by the HPCM control preparation. HPCM contains both CSFα and -β, and there is evidence that neither CSFα nor -β, acting alone, is able to stimulate all available progenitor cells.[20] The colony counts in cultures stimulated by rH GM-CSF therefore suggested that the recombinant material was not able to stimulate the proliferation of all available granulocyte-macrophage progenitors.

Morphologic analysis of day 7 colonies stimulated by rH GM-CSF showed that these were granulocytic, granulocyte-macrophage, and monocyte-macrophage colonies together with a few small eosinophil colonies (Table 1). In the cultures stimulated by rH GM-CSF, the percentage of monocyte-macrophage colonies was higher than in control cultures stimulated by HPCM. This pattern persisted at 14 days, with the most frequent colony type again being monocyte-macrophage. It should be noted that day 14 cultures stimulated by rH GM-CSF always contained prominent eosinophil colonies. In control cultures stimulated by CSFα, a similar pattern of colony formation was observed to that in cultures stimulated by rH GM-CSF, whereas in cultures stimulated by CSFβ, eosinophil colonies never developed.

Studies on the effects of rH GM-CSF were made on cultures of marrow cells from three untreated patients with acute myeloid leukemia. Cells from one of these (M2) failed to proliferate when stimulated either by HPCM or rH GM-CSF. Cells from the other two patients (M2 and M1) formed small clusters (two to 40 cells) when stimulated either by HPCM or rH GM-CSF. In both cases, the frequency (690 and 700/10^5 cells with 400 units rH GM-CSF and 640 and 650/10^5 cells with 400 units HPCM) and size of clusters developing were equivalent.

Effects of rH GM-CSF on Erythroid and Multipotential Colony Formation

No erythroid or multipotential colonies developed in agar cultures of bone marrow or peripheral blood cells stimulated by rH GM-CSF alone. However, addition of rH GM-CSF to cultures of nonadherent peripheral blood cells containing 1.5

Table 1. Morphologic Types of Colonies in Human Marrow Cultures After Seven and 14 Days of Stimulation by Human Recombinant GM-CSF

Incubation Time	Marrow Sample No.	Stimulus	Mean Number of Colonies	Percentage of Colonies			
				G	GM	M	Eosin
7 days	1	saline	0	—	—	—	—

		rH GM-CSF	99	4	31	44	21

Abbreviations: G, neutrophilic granulocyte; GM, neutrophilic granulocyte-monocyte; M, monocyte-macrophage; Eosin, eosinophil.

A total of 5 × 10^4 human marrow cells were cultured for seven or 14 days. The various stimuli (HPCM, rH GM-CSF, and CSFα and -β fractionated from U5637-conditioned medium) were all used at a concentration fourfold in excess of that stimulating maximal colony numbers to develop. The mean colony counts are from duplicate cultures. After colony counts were performed, cultures were fixed and stained with Luxol fast blue/hematoxylin, and differential colony counts were performed on the entire colonies in each culture.

units of erythropoietin consistently resulted in the formation of two- to threefold higher numbers of burst erythroid colonies than in cultures containing only erythropoietin and in the development of small numbers of multipotential colonies containing erythroid cells. Two examples of this effect are shown in Table 2, and in two other experiments similar results were obtained. A similar pattern of colony formation was observed in cultures stimulated by a mixture of HPCM and erythropoietin and in cultures containing semipurified CSFα and erythropoietin. In contrast, the combination of semipurified CSFβ with erythropoietin did not lead to an enhanced erythroid colony formation.

Titration experiments showed that enhanced erythroid colony formation could be observed with dilutions of rH GM-CSF over the same range as those able to stimulate granulocyte-macrophage colony formation by direct action.

Table 2. Enhancement of Erythroid and Multipotential Colony Formation by Recombinant Human GM-CSF

Experiment No	Stimulus	Erythropoietin	Mean Number of Colonies		
			Erythroid	Multipotential	Nonerythroid
1	saline	−	0	0	0
		+	13 ± 2	0	1 ± 1
	HPCM	−	0	0	68 ± 8
		+	55 ± 6	2 ± 1	52 ± 12

		+	12 ± 3	0	94 ± 9
	rGM-CSF	−	0	0	35 ± 10
		+	18 ± 3	1 ± 1	41 ± 9

A total of 2 × 10^6 nonadherent peripheral blood cells were cultured in 1-mL agar cultures containing 400 units of test stimulus with or without 1.5 units of semipurified human urinary erythropoietin. Cultures were scored after 14 days of incubation. Mean colony counts are ± SD of four replicate cultures.

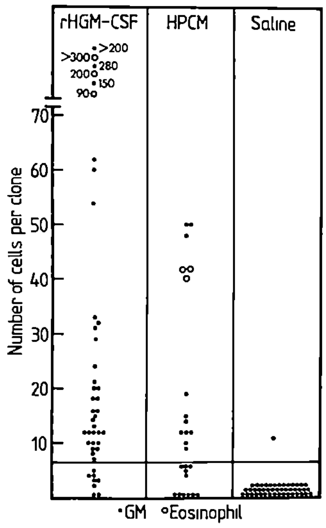

Fig 2. Behavior of four-day clones initiated by rH GM-CSF after transfer to recipient cultures containing rH GM-CSF, HPCM, or saline. The concentration of rH GM-CSF and HPCM in recipient cultures was 400 U/mL. The line indicates the mean size of clones at transfer. Note the progressive size increase in the clones after ten further days of incubation in cultures containing rH GM-CSF or HPCM.

Direct v Indirect Effects of rH GM-CSF

To determine whether the colony-stimulating effects of rH GM-CSF were the result of direct action on responding clonogenic cells, cultures were initiated using 50,000 marrow cells and 400 units of rH GM-CSF. At four days, individual clones containing four to ten cells (mean size, six cells) were removed using a fine pipette and transferred intact with minimal surrounding agar to the surface of recipient agar cultures containing 400 units of rH GM-CSF, 400 units of HPCM, or 0.1 mL saline but no cells. Analysis of the fate of these transplanted clones after a further ten days of incubation (Fig 2) showed that clone size increased progressively in recipient cultures containing both rH GM-CSF and HPCM, whereas clones died when transferred to cultures lacking CSF. Clones exhibiting progressive proliferation with continued stimulation by rH GM-CSF included both granulocyte-macrophage and eosinophil colonies, indicating that rH GM-CSF was able to act directly on responding clones of both types.

In contrast, 150 sequentially sampled clones initiated by 200 units of rH GM-CSF for five, six, or eight days in cultures of peripheral blood (clone size, three to 60 cells) generated only a single erythroid, one mixed erythroid colony, and one mixed neutrophil-eosinophil colony when transferred to cultures containing either erythropoietin or rH GM-CSF plus erythropoietin (Table 3). These results suggested that most of the enhanced erythroid colony formation seen when rH GM-CSF was combined with erythropoietin was not ascribable to an ability of rH GM-CSF, acting alone, to initiate the proliferation of some BFU-E by direct action, a property that has been documented for murine GM-CSF acting on murine BFU-E.[21]

Inactivity of rH GM-CSF on Murine Cells

Recombinant human GM-CSF failed to stimulate any type of colony or cluster formation in cultures of 75,000 C57BL bone marrow cells or 20,000 12-day CBA fetal liver cells. In cultures initiated using rH GM-CSF to which 400 units of murine Multi-CSF were added after two days of incubation, again no colonies or clusters were seen after a total incubation period of seven days. As shown in Table 4, these negative results were similar to those obtained with CSFα and were in contrast to the ability of CSFβ-containing preparations to stimulate granulocyte colony formation in cultures of adult mouse bone marrow or fetal liver cells and the weak but reproducible ability of CSFβ to initiate erythroid and multipotential colony formation when stimulation of colony formation was completed by the delayed addition of murine Multi-CSF after two days of incubation

In microwell assays using the 32D murine hematopoietic cell line (responding to murine Multi-CSF) and the murine FDC-P1 cell line (responding to both murine Multi-CSF and murine GM-CSF),[22] rH GM-CSF failed to support the survival or stimulate the proliferation of cells of either line.

Table 3. Development of Erythroid and Nonerythroid Colonies From Transfered Clones Initiated in Peripheral Blood Cultures Using rH GM-CSF

Day of Clone Transfer	Stimulus in Recipient Cultures	Number of Colonies					
		G	GM	M	Eosin	E	Mixed
5	saline	2	0	1	2	0	0
	rH GM-CSF	0	0	0	5	0	0
	rH GM-CSF + Epo	2	0	0	7	0	0
6	saline	1	0	0	1	0	0
	rH GM-CSF	1	0	0	7	0	1
	rH GM-CSF + Epo	0	0	0	6	0	1
8	saline	0	1	0	0	0	0
	Epo	1	0	0	0	1	0
	rH GM-CSF + Epo	0	0	0	5	0	0

Abbreviations. E, burst erythroid, Mixed, one colony of neutrophils and eosinophils, one colony of neutrophils, eosinophils, and erythroid cells; Epo, erythropoietin.

Clones were initiated for five, six, or eight days in cultures of 2 × 10^5 nonadherent peripheral blood cells using 200 units of rH GM-CSF. Twenty-five sequential clones of three to 60 cells were transfered to each type of recipient culture. Recipient agar cultures contained 0.1 mL saline, 200 units rH GM-CSF, and/or 1.5 units erythropoietin. Cultures were scored after a total incubation period of 14 days.

Table 4. Effect of rH GM-CSF in Cultures of Mouse Fetal Liver Cells

Stimulus	Number of Colonies Nonerythroid	 Pure or Mixed Erythroid
Cultures without addition of murine multi-CSF		
Saline	0	0
MLCM	34 ± 8	0
SCM	74 ± 25	15 ± 3
HPCM	47 ± 4	0
CSFα	2 ± 2	0
CSFβ	14 ± 1	0
rH GM-CSF	0	0
Delayed addition of murine multi-CSF on day 2		
Saline	7 ± 2	0.3 ± 0.3
MLCM	69 ± 6	10 ± 2
HPCM	85 ± 4	6 ± 4
CSFα	15 ± 9	0.5 ± 0.5
CSFβ	57 ± 18	3 ± 2
rH GM-CSF	6 ± 2	0

Abbreviations: MLCM, mouse lung-conditioned medium; SCM, pokeweed mitogen-stimulated mouse spleen-conditioned medium

Twenty thousand 12-day CBA fetal liver cells were cultured in 1-mL agar cultures containing 20% human plasma. Cultures were scored after seven days of incubation. Data are colony counts ± SD from four replicate cultures. CSFα- and -β-containing preparations were from U5637 bladder cancer-conditioned medium.

In agar cultures of 300 WEHI-3B D^+ myelomonocytic leukemic cells, rH GM-CSF and CSFα failed to induce differentiation in the leukemic colonies whereas, as previously documented,[13] CSFβ fractions exhibited high differentiation-inducing activity (Fig 3).

Binding Competition Studies

Human CSFβ is able to competitively block binding of ^{125}I-labeled murine G-CSF to either murine or human cells, whereas human CSFα has no such capacity.[13] As shown in Fig 4, rH GM-CSF had no capacity to block binding of ^{125}I G-CSF to 10^6 WEHI-3B D^+ murine myelomonocytic leukemia cells even at a concentration of 100,000 U/mL when coincubated at 37 °C for one hour.

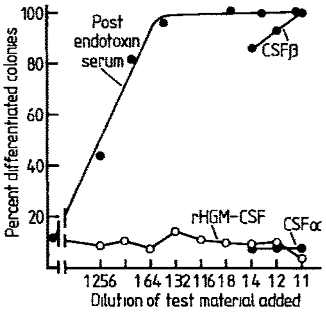

Fig 3. Failure of rH GM-CSF to induce differentiation in WEHI-3B D^+ murine myelomonocytic leukemia colonies. CSFα was also inactive, but CSFβ preparations induced differentiation comparable to that in control cultures containing postendotoxin mouse serum as a source of murine G-CSF.[23]

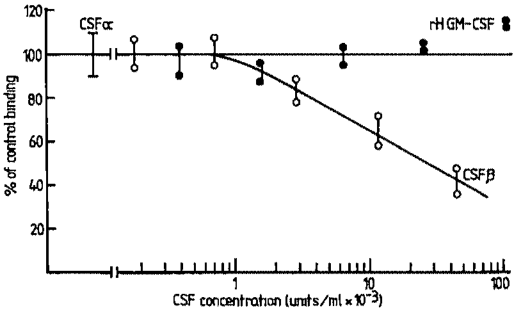

Fig 4. Failure of rH GM-CSF to block binding of ^{125}I-labeled murine G-CSF to WEHI-3B D^+ myelomonocytic leukemic cells. Note that human CSFβ competes effectively but that CSFα, like rH GM-CSF, has no competitive action (the bar indicates the labeling level in the presence of CSFα).

Stimulation of Mature Neutrophils and Eosinophils by rH GM-CSF

To determine whether rH GM-CSF was able to increase the functional activity of mature human neutrophils and eosinophils, populations of peripheral blood neutrophils (97% pure) and eosinophils (92% pure) were tested for their capacity to exhibit increased antibody-dependent lysis of ^{51}Cr-labeled tumor cells when incubated with rH GM-CSF' during the 2.5-hour assay. Control preparations were incubated with semipurified preparations of CSFα and CSFβ.

As shown in Table 5, rH GM-CSF significantly increased the lysis of tumor cells by both neutrophils and eosinophils, as did CSFα. Titration of the rH GM-CSF indicated that the 50% end point in this elevated response occurred with a concentration of approximately 60 pg/mL, a tenfold lower concentration than that usually stimulating 50% maximal colony formation. In agreement with previous observations,[17] preparations containing CSFβ had no effect on eosinophil-mediated killing and only stimulated neutrophil-mediated killing.

CSFα, but not CSFβ, has previously been shown to increase eosinophil autofluorescence.[18] As shown in Table 6,

Table 5. Stimulation by rH GM-CSF of Antibody-Dependent Cytolysis of ^{51}Cr-Labeled P815 Mastocytoma Cells by Human Eosinophils and Neutrophils

Stimulus	Percentage of Cytotoxicity* Eosinophils (92% pure)	 Neutrophils (97% pure)
Saline	0.7†	2.1
rH GM-CSF	39.5	11.9
CSFα	22.9	12.7
CSFβ	0.2	10.8

*There was no significant release of ^{51}Cr in the absence of antibody by target cells.

†Arithmetic mean of triplicate determinations. The eosinophil cytotoxicity stimulated by rH GM-CSF and CSFα was significantly higher ($P < .001$) than that stimulated by CSFβ or exhibited by control cells to which saline had been added. The neutrophil cytotoxicity stimulated by rH GM-CSF, CSFα, and -β was significantly higher ($P < .001$) than that of unstimulated cells.

Table 6. Ability of rH GM-CSF to Increase Autofluorescence of Human Eosinophils

Stimulus	Percentage of Increased Autofluorescence *v* Control Cells*
rH GM-CSF	36 ± 16
CSFα	37 ± 12
CSFβ	−1 ± 13

*Calculated from FACS analysis above an arbitrary channel number.[18]

rH GM-CSF at a concentration of 2 ng/mL had the same ability to increase the autofluorescence of eosinophils.

As shown in Table 7, incubation of purified neutrophils in the presence of 2 ng/mL rH GM-CSF for one hour significantly increased their capacity to phagocytose yeast organisms

DISCUSSION

In agreement with the original biologic monitoring experiments[2] undertaken during the cloning of the cDNA for human GM-CSF, the present experiments have indicated that rH GM-CSF, as synthesized by monkey COS cells, is an effective proliferative stimulus for human granulocyte-macrophage progenitor cells leading to typical colony formation in semisolid cultures. In addition, however, the present experiments have shown that rH GM-CSF is also a highly effective proliferative stimulus for human eosinophil colony formation. Plateau levels of granulocyte-macrophage and eosinophil colonies were stimulated by a concentration of 1 to 5 ng/mL rH GM-CSF, and minimum colony formation was observable with 300 pg/mL. The overall level of colony-stimulating activity in the purified material was calculated as at least 4 × 10^7 U/mg, a figure in agreement with the previous estimate[2] and reasonably similar to the specific activity of the four purified murine granulocyte-macrophage CSFs in bone marrow cultures, which vary from 10^8 to 10^9 U/mg.[1] The rH GM-CSF exhibited somewhat stronger stimulating activity for monocyte-macrophage colony formation than for granulocyte colony formation. This, coupled with the fact that the plateau numbers of colonies, particularly at day 7, were always lower than with HPCM, suggests that rH GM-CSF is not able to stimulate the proliferation of all GM progenitors and may in fact stimulate the same subset as stimulated by CSFα.

A prominent feature of the action of rH GM-CSF was the stimulation of eosinophil colony formation. Eosinophil colony formation has previously been observed in cultures stimulated by semipurified CSFα preparations,[11] but an alternative possible explanation of these earlier observations was that the eosinophil colony formation was due to the presence in the preparations of a contaminating eosinophil CSF. The present results with purified GM-CSF of recombinant origin clearly indicate that this molecule possesses the capacity to stimulate eosinophil colony formation and suggests that the previously observed activity of CSFα-containing preparations was not due to a contaminating eosinophil CSF.

Table 7. Stimulation by rH GM-CSF of Phagocytosis of Yeast Organisms by Peripheral Blood Neutrophils

Incubated With	Number of Cells Scored	Percentage of Cells With Indicated Numbers of Yeast Organisms					
		0	1	2	3	4	≥5
Buffer	600	56	15	11	10	5	3
rH GM-CSF	600	22	22	24	15	11	6

The rH GM-CSF was used at a final concentraton of 2 ng/mL. The incubation time was one hour. The results are significantly different by χ^2 analysis ($P < .001$).

No erythroid colonies were observed in cultures stimulated by rH GM-CSF. However, combined stimulation by rH GM-CSF and erythropoietin of nonadherent peripheral blood cells led to the formation of increased numbers of pure burst-erythroid colonies and occasional multipotential colonies containing erythroid cells.

Analysis using clone transfers indicated that the actions of rH GM-CSF on granulocyte-macrophage and eosinophil colony formation were direct effects on the CSF, acting alone, on responding clonogenic cells. However, transfer experiments using clones initiated by rH GM-CSF showed that most of the enhanced erythroid colony formation in cultures containing rH GM-CSF and erythropoietin seemed not to be ascribable to a direct action of rH GM-CSF in initiating proliferation of BFU-E. Thus the situation with rH GM-CSF differs from that documented previously for murine GM-CSF in which it was possible to demonstrate a direct action of GM-CSF on a major fraction of murine BFU-E.[21] The basis for the observed erythroid enhancement requires further investigation. Two possibilities needing investigation are (1) that rH GM-CSF and erythropoietin need to act simultaneously on BFU-E or (2) that the action of rH GM-CSF may be indirect and be mediated by stimulation of some other cell type in the culture to produce an erythroid-enhancing factor.

Tests using mature human neutrophils and eosinophils showed that rH GM-CSF was an effective stimulus of antibody-dependent cytotoxicity for tumor target cells, increased phagocytic activity by neutrophils, and increased eosinophil autofluorescence—general properties noted previously for human-active CSFs.[17,18] These observations on the effects of rH GM-CSF on mature end cells are in agreement with a recent study[10] indicating that this molecule, as purified from Mo cell–conditioned medium, has an ability to act on mature neutrophils as monitored by the inhibition of neutrophil migration.

The rH GM-CSF had no capacity to stimulate the proliferation of murine hematopoietic cells from either marrow or fetal liver cells or of cells of two murine continuous cell lines responding to murine Multi-CSF or GM-CSF. Furthermore, no differentiation-inducing activity was noted when rH GM-CSF was added to cultures of the murine myelomonocytic cell line WEHI-3B.

A summary of the observed biologic activity in parallel assays of rH GM-CSF compared wtih those of semipurified human CSFα and -β is presented in Table 8. It is clear that the activities of rH GM-CSF differ completely from those of CSFβ-containing material, and recent studies have in fact shown that murine G-CSF, not GM-CSF, is the functional analogue of human CSFβ.[13] The activities of rH GM-CSF

Table 8. Comparison of Range of Biologic Activities of rH GM-CSF, Human CSFα and Human CSFβ

Biologic Activity	Type of Human CSF		
	rH GM-CSF	CSFα	CSFβ
Stimulation of			
7D GM colonies	+	+	++
14D GM colonies	++	++	+
Eosinophil colonies	++	++	0
Potentiation of erythroid and multipotential colonies	+	+	0
Stimulation of murine GM colonies	0	0	++
Initiation of murine erythroid and mixed colonies	0	0	+
Induction of differentiation in murine leukemic cells	0	0	++
Binding competition with murine G-CSF	0	0	++
Stimulation of mature cell function			
Neutrophil	++	++	++
Eosinophil	++	++	0

are identical to those of CSFα-containing preparations, and it can be concluded provisionally that rH GM-CSF is CSFα. Verification of this conclusion should be possible since GM-CSF with the same *N*-terminal sequence has been purified from Mo cell–conditioned medium,[2,3] and the properties of this purified native molecule need to be determined using the aforementioned broad range of assay systems.

The purification has been reported of a human pluripoietin from medium conditioned by the bladder cancer cell line, U5637.[24] From its reported ability to stimulate erythroid, multipotential, granulocyte-macrophage and to induce differentiation in murine myeloid leukemia cells, this pluripoietin does not resemble CSFα, CSFβ or rH GM-CSF. Furthermore, if it has any homology with murine multi-CSF at the amino acid sequence level, it would be unlikely to have homology with rH GM-CSF since there is no homology between murine GM-CSF and multi-CSF.[4] Therefore, despite the ability of rH GM-CSF to promote erythroid colony formation and the formation of some mixed erythroid colonies, it is unlikely that rH GM-CSF is a candidate human analogue of murine multi-CSF. In this context, murine GM-CSF also potentiates erythroid and mixed colony formation, in this case by being able to initiate (but not sustain) the proliferation of erythroid and multipotential precursors.[21] Previous studies have shown that murine GM-CSF is also able to stimulate eosinophil colony formation by adult and particularly fetal progenitor cells.[25,26] Thus, the ability of rH GM-CSF to stimulate the proliferation of human eosinophil precursors does not make it different in principle from its murine analogue.

Purified rH GM-CSF should be an effective agent for routine use in stimulating colony and cluster formation in cultures of human normal cells and in stimulating the functional activation of mature human neutrophils and eosinophils. Subject to more extensive testing, this agent may also be a useful proliferative stimulus for use in cultures of myeloid leukemic cells. However, from the present data using normal granulocyte-macrophage progenitor populations, it needs to be emphasized that rH GM-CSF is likely not to be able to stimulate the proliferation of all available progenitor cells. To achieve this latter result it will be necessary to produce recombinant human CSFβ and, if additional human CSFs exist, recombinant versions of these and to use a mixture of such recombinant CSFs for routine use so that all available progenitor cells are able to be stimulated.

If recombinant GM-CSF material with equivalent biologic activity to the present material can be generated using yeast or bacterial expression systems, the prospects are good that it will become possible to test the in vivo actions of this regulator in clinical situations when there is a need either to stimulate increased cell production or to stimulate the functional activity of existing mature cells.

ACKNOWLEDGMENT

The authors are indebted to Cathy Quilici, Yvonne Wiluszynski, Deborah Luxenberg, and JoAnn Witek-Giannotti for careful technical assistance in these experiments.

The authors thank Dr A W. Burgess, Ludwig Institute for Cancer Research, Melbourne Branch, for generously supplying the batches of purified murine GM-CSF and M-CSF used in these experiments.

Sickle Cell Anemia Patients Have Low Erythropoietin Levels for Their Degree of Anemia

By Judith B. Sherwood, Eugene Goldwasser, Robert Chilcote, L. David Carmichael, and Ronald L. Nagel

We have studied serum immunoreactive erythropoietin (SIE) levels in 28 patients with sickle cell anemia (SCA) without renal insufficiency and in 17 patients with nonhemoglobinopathy anemias of comparable severity using a sensitive radioimmunoassay procedure. An exponential relationship between SIE level and degree of anemia was noted in all patients. However, in nonhemoglobinopathy anemia, a sharp rise in the SIE level occurred as hemoglobin (Hb) levels fell below about 12 g/dL, whereas in sickle cell patients the increase was not marked until hemoglobin fell to about 9 g/dL. The response was more blunted in older SCA patients than in younger ones. A linear regression model relating SIE level to Hb level, presence/absence of SCA, and age explained 63% of the variation in SIE. We conclude that the serum erythropoietin levels in SCA increased at a lower hemoglobin concentration and are of a lower magnitude than that of the other anemias.

© 1986 by Grune & Stratton, Inc.

A CONSIDERABLE NUMBER of clinical and experimental observations demonstrate the inverse relationship between the erythropoietin level in plasma and urine and the level of tissue oxygenation.[1] A direct correlation between elevated erythropoietin levels and the degree of hypoxic stimulus has been shown[2,3] as well as suppression of erythropoietin levels with hyperoxia[4] or red cell plethora.[5] The inverse relationship between the red cell mass and hemoglobin concentration, and the circulating erythropoietin titer, has been amply demonstrated.[1,6]

The erythropoietin response in several anemias has been more difficult to establish, in part because of the lack of precision of the bioassay methods heretofore available and because of parameters of the specific anemia such as $Hb\text{-}O_2$ affinity, renal damage, etc.

We have studied the correlation between erythropoietin levels and hemoglobin concentrations in patients with sickle cell anemia who have red cells with low oxygen affinity as well as in patients with anemias not associated with hemoglobinopathies. We have used the sensitive and specific radioimmunoassay for erythropoietin,[7] which allows the accurate measurement of normal and depressed levels of human serum erythropoietin without prior concentration of samples. Finally, we have examined the effect of age on the Hb level–erythropoietin relationship.

MATERIALS AND METHODS

Subjects. Serum was obtained from patients with anemias of various causes. 28 patients had sickle cell disease (ten adults and 18 children and young adults). Two additional subjects with $S\beta^+$-thal were also studied. Of the 18 children and young adults with sickle cell disease, 12 were males and six females, and they had a mean age of 9.2 ± 5.5 years with a range of 1 to 17. Their mean hemoglobin level was 7.6 ± 1.6 g/dL with a range of 3.1 to 10.1 g/dL; the reticulocyte count was 19.4% ± 10.1% with a range of 0.1% to 36.3%. All patients had a BUN less than 20 mg/dL. Of the ten adult patients with sickle cell anemia, seven were females and three males; they had a mean age of 31.0 ± 6.6 years with a range of 22 to 40 years. Thirteen patients had anemias not associated with hemolysis nor with any hemoglobinopathy; three patients had chronic lymphocytic leukemia, one had chronic myelocytic leukemia, four had multiple myeloma, and five had anemias not associated with hematologic malignancy. All of the patients with non–sickle cell anemia had normal BUN levels (mean, 16.1 ± 3.42 mg/dL) and serum creatinine levels less than 2 mg/dL. Four patients had hemolytic anemias not associated with hemoglobinopathy. None of these patients had been transfused and all had a BUN less than 20 mg/dL. The two pediatric patients with $S\beta^+$-thal had a mean age of 7 ± 2 years, a mean hemoglobin level of 7.6 ± 0.65 g/dL, a reticulocyte count of 15.2% ± 4.8%, a mean corpuscular volume (MCV) of 71.5 ± 0.5 μm^3, a mean corpuscular hemoglobin (MCH) of 24.8 ± 0.45 pg, a mean corpuscular hemoglobin concentration (MCHC) of 35% ± 0.95%, and a bilirubin level of 0.7 ± 0.7 mg/dL. All hematologic and other laboratory data of these patients are shown in Table 1. Blood was allowed to clot on ice for two hours. The serum was separated by centrifugation and stored at −20 °C until assay.

Assay procedures. Serum immunoreactive erythropoietin (SIE) was measured in each serum sample by using the radioimmunossay procedure described by Sherwood and Goldwasser.[7] Erythropoietin was labeled with ^{125}I by using the water-insoluble oxidizing agent Iodogen (Pierce Chemical Co, Rockville Ill).[8] The iodinated tracer was incubated with erythropoietin standard or 100 μL of serum sample and with antiserum in a phosphate buffer diluent. The antiserum was used at a dilution that gave a bound-to-total ^{125}I-erythropoietin ratio (B/T) between 0.20 to 0.30. The antibody-erythropoietin complex was separated from the free hormone either by precipitation with ammonium sulfate by using a modification of the method developed by Stanley[9] or by use of the second antibody technique previously described.[7]

Statistical analysis. Preliminary examination of the data revealed a nonlinear relationship of the SIE level to varying degrees of anemia, with nonuniform variances proportional to the mean SIE level (Table 1). Therefore, a log-linear model with a nonzero asymptote of the form $\log(SIE_i - C) = b_0 + b_1(Hb_i) + e_i$ was chosen, and the other patient variables (age, presence of sickle cell disease, and other hematologic characteristics) were evaluated for their contribution by standard regression analysis.[10] The asymptote c was set at 10 mU/mL, approximating the normal mean −2 SD as established in this laboratory's assay. This procedure allowed us to select variables that significantly affected the SIE level, with approximately normal distribution of error terms and an F value for the model of 22.0 ($P < 2 \times 10^{-8}$).

Abbreviations: Hct, hematocrit; EPO, erythropoietin; Hb, hemoglobin

Values are expressed as mean ± SD. Numbers in parentheses are the range of values. Hematologic indexes (MCV, MCH, MCHC) were obtained by the Coulter Counter (Coulter Electronics, Hialeah, Fla). Erythropoietin values were determined in the radioimmunoassay.

RESULTS

SIE levels were measured in 17 patients with anemias of various causes not associated with sickle cell anemia, other hemoglobinopathies, or renal disease (including four patients with hemolytic anemia) and in 28 patients with sickle cell anemia (ten adults and 18 children); of these, the 17 non–sickle cell anemia patients and 26 sickle cell anemia patients for whom all variables were recorded were used in the analysis. The two patients with Sβ^+-thal were analyzed separately. We found that Hb level, age, and sickle cell anemia status predicted 63% (R^2) of the variance in SIE (Figs 1 and 2), with $F_{3,39} = 22.0$ ($P < 2 \times 10^{-8}$). The significance of the contribution of the individual terms was tested, and presence/absence of sickle cell anemia was highly significant ($P < .0004$); the effect of age, however, was significant only among sickle cell anemia patients ($P \cong .011$). The adult sickle cell anemia patient with 220 mU/mL of SIE appeared to be an outlier; however, there were no major alterations in the model when this patient was excluded, and there appeared to be no technical reasons to question the accuracy of the SIE determination.

The mean SIE level of the anemic patients was significantly higher than the normal value of 21 ± 6 ($\bar{x}$ ± SD) mU/mL previously found with this radioimmunoassay.[7,11] The 17 patients with nonhemoglobinopathy-associated anemias had the highest levels: 414 ± 327 mU/mL of serum (range, 21 to 1,300 mU/mL), with a mean hemoglobin concentration of 9.7 ± 2.5 g/dL (range, 6.1 to 12.8 g/dL). The mean SIE level of the four patients with hemolytic anemias not associated with hemoglobinopathy was 395 ± 195 mU/mL (range, 220 to 610 mU/mL), a value that did not differ significantly from the levels found in the other nonhemoglobinopathy anemias (Fig 1). The mean value found for the patients with sickle cell anemia was 144 ± 234 mU/mL of serum (range 12 to 1,300 mU/mL), with a mean hemoglobin concentration of 7.8 ± 1.5 g/dL (range, 3 to 11 g/dL). As shown in Fig 2, the sickle cell anemia patients have less SIE at any level of hemoglobin; SIE levels rise only when considerably lower Hb levels are reached, as compared with non–sickle cell anemia patients.

The adult sickle cell anemia patients had a mean SIE level of 56 ± 63 mU/mL of serum (range, 12 to 220 mU/mL)

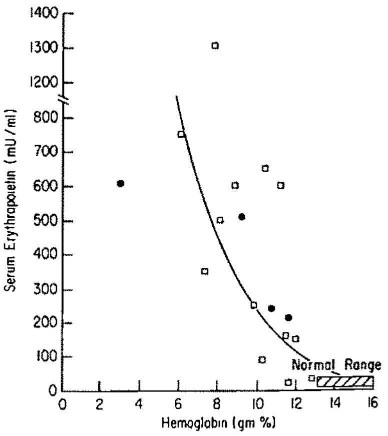

Fig 1. Erythropoietin levels in nonhemoglobinopathy anemias for 13 patients with nonhemolytic (□) and four patients with autoimmune hemolytic (●) anemia. The line represents the regression equation log (SIE − 10) = 8.91 − 0.35 (Hb), and the crosshatched box indicates the normal range.

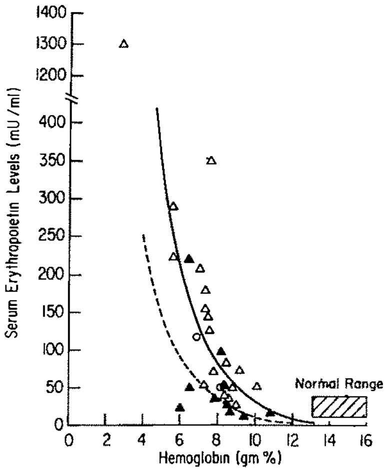

Fig 2. Erythropoietin levels in sickle cell anemia for 18 pediatric (△) and ten adult (▲) patients; two children with Sβ^+-thal disease (O) are also shown. The regression equation log (SIE − 10) = 8.91 − 0.54 (Hb) − 0.04 (age) is shown for the mean age of the two age groups.

with a mean hemoglobin concentration of 8.1 ± 1.5 g/dL (range, 6 to 11 g/dL). The children with sickle cell anemia, with a similar hemoglobin concentration of 7.6 ± 1.6 g/dL (range, 3 to 10 g/dL), had a mean SIE level of 193 ± 292 mU/mL of serum (range, 27 to 1,300 mU/ml). When a child with 3 g/dL hemoglobin and an erythropoietin level of 1,300 mU/mL was excluded, the mean SIE level for the children was 127 ± 96 mU/mL, and the mean hemoglobin level was 7.9 ± 1.1 g/dL. Analysis of covariance comparing the adult and pediatric sickle cell patients showed that the average erythropoietin level was significantly different at $P < .02$, even when the child with the very low hemoglobin level (3.1 g/dL) and high erythropoietin level (1,300 mU/mL) was not included in the computation.

The two children with $S\beta^+$-thal had a mean Hb level of 7.6 ± 0.65 g/dL and an SIE level of 84.2 ± 33.8 mU/mL (50.5, 118). When they were included in the regression model, there was no significant alteration in its parameters, and its strength actually increased slightly ($R^2 = 65\%$)

DISCUSSION

SIE levels were determined in pediatric and adult patients with sickle cell disease and in patients with nonhemoglobinopathy anemias of various causes, including hemolytic anemias by using our sensitive radioimmunoassay procedure.[7] An exponential relationship between the SIE level and the hemoglobin concentration was noted in all patients. In patients with nonhemoglobinopathy anemias, we observed a drastically increased slope at a hemoglobin concentration of approximately 11 g/dL or less (Figs 1 and 2). This hemoglobin level can be considered as a threshold. The data presented here on the inverse relationship between hemoglobin concentration and immunoreactive erythropoietin levels in anemias other than sickle cell (Fig 1) are in general agreement with the previously published data based on biologic activity.[12]

The relationship between Hb levels and SIE in the sickle cell anemia patients departs from this since these patients exhibit elevated levels of erythropoietin only at a hemoglobin concentration below about 9 g/dL (Fig 2). The patients with nonhemoglobinopathy-associated anemias and other types of hemolytic anemias do not exhibit this hemoglobin threshold and have levels of SIE that are greater than that of the sickle cell patients (Fig. 2). Our observation that patients with sickle cell anemia produce less immunoreactive erythropoietin at a given hemoglobin concentration than do patients with nonhemoglobinopathy anemias (hemolytic and nonhemolytic) agrees with a previous observation using the biologic assay.[13]

We conclude that the relationship between SIE and Hb levels in sickle cell anemia can be described by an exponential curve that is significantly displaced to the left. In addition, the level of SIE reached by these patients is also significantly lower than that observed in other anemias. Analysis of the variables involved in the relationship between SIE and Hb levels by using a linear regression model indicated that age, Hb level, and presence or absence of anemia explained 63% (R^2) of the variance in the SIE level. Of special interest is the effect of age, as pediatric sickle cell anemia patients tended to have significantly higher SIE levels than adults. The potential mechanism for the low SIE levels in sickle cell disease include interference with the renal synthesis of erythropoietin and the displacement to the right of the O_2 equilibrium curve.

The well-known right shift in the oxygen equilibrium curve would facilitate oxygen delivery to the tissues, decreasing the hypoxic burden of a given level of anemia. Sickle cells have a higher p50 because of the intrinsically lower affinity for oxygen of the hemoglobin S polymer[14] and because of the increase in intracellular 2,3-diphosphoglyceric acid levels.[15] In addition, kinetic factors (decreased uptake and diffusion of O_2) contribute to this anomaly in vivo.[16]

Renal tissue damage in these patients might compromise the synthesis of erythropoietin or the hypoxia sensor presumed to be located in this organ. The renal damage, which differs from renal insufficiency, involves a concentration defect, progressive vascular damage particularly to the medulla, and structural abnormalities of the glomeruli and tubules.[17] In favor of this interpretation is the age dependency of the level of SIE in sickle cell anemia patients (Fig 2). Individuals with chronic renal failure have SIE levels that are higher than normal, but lower than expected for the degree of anemia.[18] In addition, Morgan et al[13] observed that in adults with sickle cell anemia the concentration of erythropoietin was correlated positively with creatinine clearance and inversely with the BUN and that hemoglobin concentrations were depressed in the presence of minor degrees of renal insufficiency. Further work is necessary to establish definitively the mechanism of the decreased erythropoietin response in the patient with sickle cell anemia.

ACKNOWLEDGMENT

We are grateful for the help of Dr Christine Lawrence and Dr Parviz Lalazari in securing samples for this work. The technical contributions of Sandra Ewert and Annette Gardner and the secretarial assistance of Elizabeth Ezzone are gratefully acknowledged

A Monoclonal Antibody Reactive With Human Eosinophils

By Hiroshi Saito, Kazuyoshi Yamada, Jacqueline Bréard, Osamu Yoshie, and Georges Mathé

EO-1, an IgGI murine monoclonal antibody raised against human eosinophilic leukemia cells, reacts with eosinophils, basophils, platelets, and a few (2%) mononuclear cells but not with neutrophils. In the bone marrow, mature and immature eosinophils and basophils express the EO-1 antigen, whereas immature myeloid cells do not. The distribution of EO-1 antigen on leukemic cells is concordant with this finding, ie, typical myeloid lines (HL-60, KG-1, and ML-1) and fresh acute myelogenous leukemia cells are all unreactive with EO-1. Immunoprecipitation of an extract from surface-^{131}I-labeled platelets with EO-1 and sodium dodecyl sulfate polyacrylamide gel electrophoresis, under reducing or nonreducing conditions, yielded a specific band of molecular weight 23,000. Previously described monoclonal antibodies reacting with eosinophils also recognize neutrophils. EO-1 is a unique antibody with specificity restricted to eosinophils, basophils, and platelets and might therefore be a valuable reagent for the study of their function and differentiation.

© 1986 by Grune & Stratton, Inc.

MANY MONOCLONAL antibodies that react with peripheral blood (PB) granulocytes have been reported. Some of these, PM-81, FMC10, and 3G8,[1–4] react with both neutrophils and eosinophils, whereas others are specific only for neutrophils (My-1, IB5, 4D1).[5,6] Antibodies such as B37.3[7] recognize neutrophils and platelets, whereas ANH7 is specific for neutrophils, eosinophils, and basophils.[8] Thus far there has been no report of a monoclonal antibody that reacts with eosinophils but not with neutrophils. Such an antibody would be a useful reagent for analyzing eosinophil function and differentiation. This report concerns the generation of such an antibody, termed EO-1.

MATERIALS AND METHODS

Production of monoclonal antibody The EO-1 cell line was established by the fusion of NS-1 myeloma cells with spleen cells from Balb/c mice immunized with eosinophils purified from a patient with eosinophilic leukemia by using the method of Köhler and Milstein[9] as previously described.[10]

Isolation of peripheral mononuclear cells and spleen cells Peripheral mononuclear cells (MNC) and spleen cells were isolated by Ficoll-metrizoate (F/M) (Lymphoprep, Nyegaard, Sweden) density gradient centrifugation. The T cell fraction (E+, cells forming rosettes with sheep erythrocytes) and T cell depleted fraction (E−, cells not forming rosettes with sheep erythrocytes) were prepared as described previously.[10] Monocytes were obtained by adherence to plastic dishes pretreated with fetal calf serum.[11]

Isolation of eosinophils, basophils, and neutrophils Erythrocytes were separated from whole PB by sedimentation in 30% Plasmasteril (Fresenius, Hamburg, Germany), and the buffy coat was collected. The separation of eosinophils and neutrophils was carried out according to the procedure described by Ellis et al[12] with a slight modification. The buffy coat cells were spun on a Percoll (Pharmacia Fine Chemicals, Uppsala, Sweden) discontinuous density gradient, using four different concentrations of Percoll (56%, 64%, 68%, and 77%). The neutrophils were collected on the 68% Percoll layer and eosinophils on the 77% layer. A cell fraction relatively enriched in basophils was obtained on top of the 64% Percoll layer In all cases, purity was assessed by morphology or reactivity with the lineage-specific monoclonal antibodies OKT3 (Ortho Pharmaceutical Corp, Raritan, NJ) B1, I2, Mo1, Mo2 (Coulter, Hialeah, Fla), HNK-1 (Becton Dickinson), IF10,[10] and surface immunoglobulin (SmIg). J5 antibodies were kindly provided by Dr J Ritz (Harvard University, Boston). Platelets were prepared by centrifugation of whole blood for ten minutes at 250 g.

Flow cytofluorimetric analysis A total of 10^6 cells were incubated with EO-1 antibody at 4 °C for 30 minutes, washed twice in phosphate buffered saline (PBS) containing 0 1% bovine serum albumin and 0.05% sodium azide, and incubated with 25 μL of fluorescein-conjugated F(ab')$_2$ goat antimouse immunoglobulin (Cappel Laboratories, Cochranville, Pa) for 30 minutes at 4 °C. The cells were then washed and suspended in 1 mL of PBS. Stained cells were analyzed with a cell sorter (CS-2,000, Showa Denko, Tokyo). The intensity of fluorescence per cell was recorded by a multiple-channel pulse-height analysis. As a control for all experiments, a murine monoclonal IgGI antibody that specifically reacts with a cytoplasmic antigen was used

Cell fractionation by the immune rosette technique In some experiments, cells were separated into immune rosette-positive and -negative fractions as previously described.[10] Briefly, F/M MNC or bone marrow (BM) cells were incubated with specific antibody for 30 minutes on ice and washed three times with PBS. Ox or sheep erythrocytes coupled with Fab-antimouse immunoglobulin antibody (IgG) (Cappel Laboratories) by the chromium chloride method[13] were added to these suspensions. The mixture was centrifuged at 400 g for five minutes. The percentage and morphology of rosette-forming cells were analyzed. This method was used for the identification of cells reacting with the EO-1 antibody and also for the preparation of lymphocyte subsets.

Human leukemic cell lines. Cell lines (T cell lines: CEM, JM, MOLT4F, HSB, HPB; B cell lines: DAUDI, RAJI, P3HR1, BALL-1, RPMI 8866, SERAFINA, RAEL, ARH77; Pre-B or null cell lines: NALM-1, NALM-6, NALM16, Reh; Myeloid-monocytic lines: K562, HEL, HL-60, KG-1, ML-1, ML-2, THP-1, U937) were maintained in suspension culture as previously described.[10]

Human leukemic cells. Leukemic cells from PB or BM from patients with acute lymphocytic leukemia (ALL), acute myelogenous leukemia (AML), chronic lymphocytic leukemia (CLL), chronic myelogenous leukemia (CML), CML–blastic crisis (CML-BC), basophilic leukemia, and Burkitt's lymphoma were tested for reactivity with EO-1.

Characterization of EO-1 antigen. Cell surface antigens of intact platelets isolated from a healthy donor were radioiodinated by the lactoperoxidase technique using carrier-free Na^{131}I (2 mCi, Amersham Corp, Oakville, Canada)[14] The cell membranes were solubilized for 30 minutes in a lysis buffer (PBS containing 0 5% Nonidet P-40 [Sigma Chemical Co, St Louis]) and 1 mmol/L phenylmethylsulfonyl fluoride on ice, and the lysate was centrifuged

at 10,000 rpm for five minutes. Radiolabeled extracts were precleaned by incubation with protein A–Sepharose 4B(Pharmacia) for four hours. The cleared extract was incubated with 10 μL of monoclonal antibody (ascites fluid) of EO-1 or control ascites for one hour at 4 °C and then incubated with protein A–Sepharose 4B overnight at 4 °C. The gels were then washed three times with PBS, and the immune complex was eluted with the sodium dodecyl sulfate (SDS) sample buffer for electrophoresis. The eluates were boiled for two minutes and electrophoretically analyzed by 10% SDS polyacrylamide gel electrophoresis (PAGE) according to the methods of Laemmli.[15] The gels were stained, dried, and subjected to autoradiography.

RESULTS

Selection of monoclonal antibody. One supernatant EO-1 that reacted with eosinophils but not with neutrophils was selected. EO-1 cells were cloned by a limiting dilution, and ascites were generated. The immunoglobulin class of EO-1 antibody was determined by the Ouchterlony method as IgG1.

Cytofluorimetric analysis. The fluorescence intensity profile showed intense staining of the majority of eosinophils, and the percentage of positive eosinophils by the cell sorter was concordant with that calculated by the standard morphologic method. As shown in Figs 1A and 1B, the higher the content of eosinophils in the fraction, the more prominent were the cells positive with EO-1. The majority of neutrophils did not react with EO-1. The small number of MNC in the PB seemed to be positive with EO-1 (Fig 1C), and a small fraction of BM cells also reacted with EO-1 (Fig 1D). Monoclonal antibody used for the control did not show any reaction.

Reactivity of EO-1 with eosinophils and basophils by the immune rosette method. Eosinophils prepared by Percoll fractionation from normal PB were tested for their reactivity

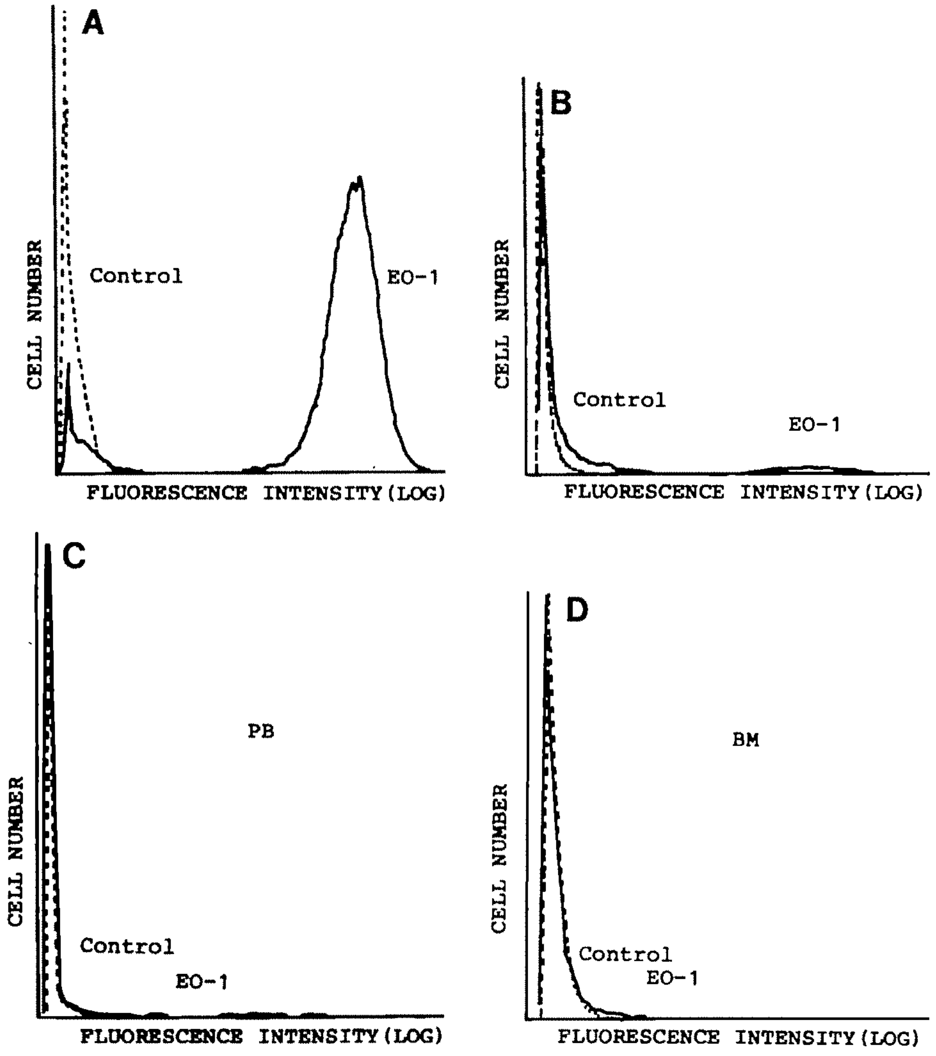

Fig 1. Reactivity of EO-1 on various cell fractions from (A) eosinophils purified from PB by Percoll gradient (77%) (purity: eosinophils, 94%; neutrophils, 6%), (B) neutrophils purified from PB by Percoll gradient (66%) (purity: neutrophils, 87%; eosinophils, 10%; lymphocytes, 3%) (C) MNC of PB, and (D) BM cells. Cells were stained with EO-1 and were assessed by indirect IF with flow cytometry. The dotted line in A to D represents the fluorescence profile of cells stained with control ascites. (A) Ninety-one percent of the cells were positive with EO-1. (B) Thirteen percent of the cells were positive with EO-1.

with EO-1 by the immune rosette test. This was used rather than the cell sorter technique since it permitted the morphologic study of positive and negative cells by preparing and staining smears of the rosetting mixture. Examination of such smears showed that all rosetting cells were eosinophils (Fig 2a) and that a mean of 47.5% of the total number of eosinophils was positive (Table 1). No neutrophils formed rosettes. Eosinophils were also purified with a Percoll gradient from one CML patient's PB since the number of eosinophils is relatively high in this disease. Eighty-eight percent of these eosinophils formed rosettes with EO-1. Moreover, when such rosetting mixtures were sedimented over a Percoll gradient (77%), nonrosette cells were seen to be composed exclusively of neutrophils (Fig 2b). The contaminating eosinophils present in this fraction were also rosette-positive. Most rosette-positive cells recovered at the bottom of the Percoll gradient after lysis of red blood cells were eosinophils (Fig 2c).

To test the reactivity of EO-1 with basophils, relatively enriched preparations (1% to 2% basophils) were obtained by Percoll fractionation of normal PB. We found that most basophils formed immune rosettes with EO-1 (Table 1, Fig 2d). Purified platelets reacted positively with EO-1 in all cases, but the monoclonal antibody used for the control studies did not form any rosettes.

EO-1 antibody was tested against normal (three samples) and CML (two samples) human BM cells separated on F/M gradient. About 5% of the nucleated cells were EO-1–positive in both the normal and CML samples. Of these positive cells, the majority were mature or immature eosinophils (Fig 2e). The remaining positive cells were basophils and a few small lymphoplasmacytoid cells. Neutrophils, myelocytes, and promyelocytes did not react with EO-1. Eosinophils were further purified from the BM of the two CML cases by Percoll sedimentation. The percentages of eosinophils forming rosettes in the two samples were 98% and 53%, respectively (Table 1).

Expression of EO-1 antigen on normal peripheral MNC. A small but regularly detectable percentage of EO-1–positive cells is present in normal MNC (Table 2). We attemped to determine the nature of these cells by fractionating MNC into various subsets and studying their reactivity

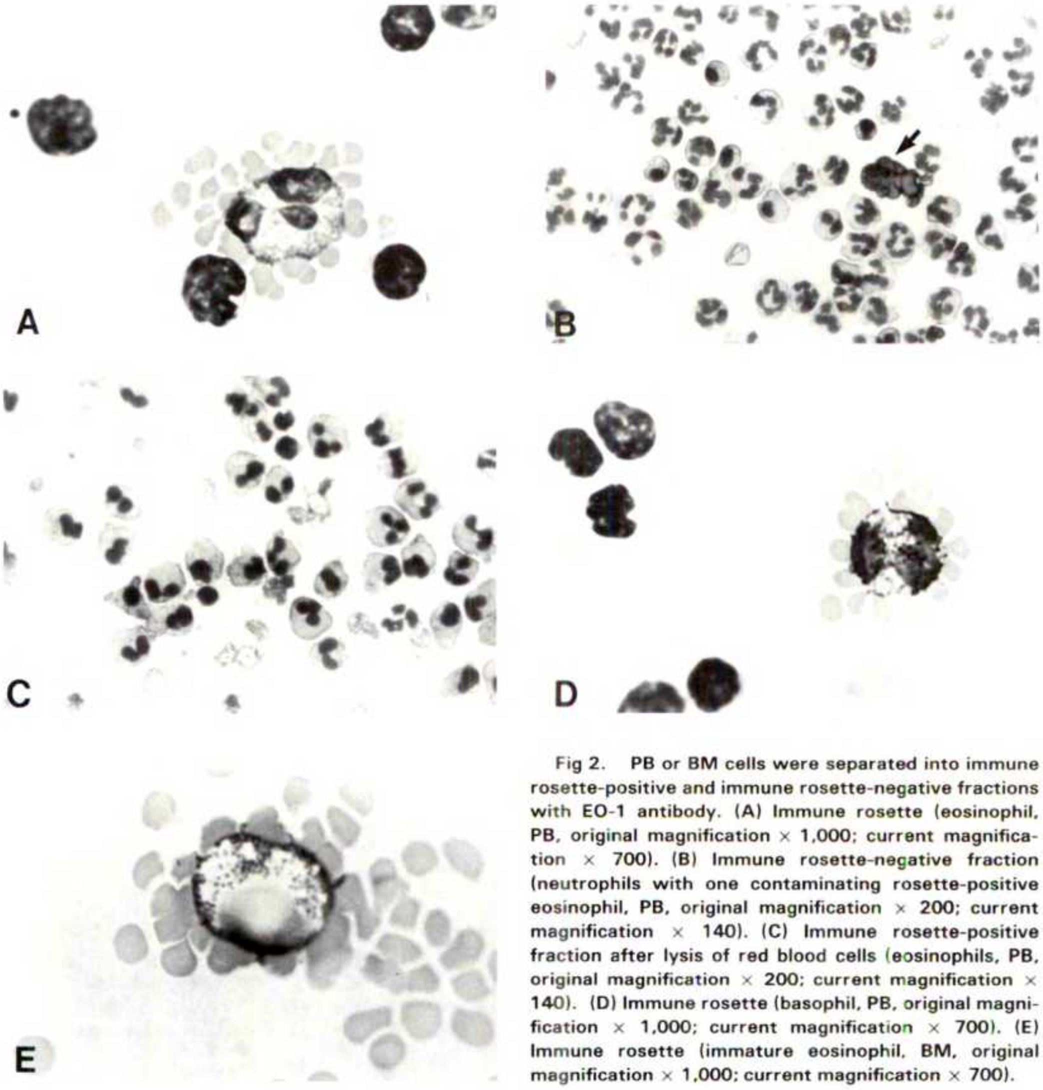

Fig 2. PB or BM cells were separated into immune rosette-positive and immune rosette-negative fractions with EO-1 antibody. (A) Immune rosette (eosinophil, PB, original magnification × 1,000; current magnification × 700). (B) Immune rosette-negative fraction (neutrophils with one contaminating rosette-positive eosinophil, PB, original magnification × 200; current magnification × 140). (C) Immune rosette-positive fraction after lysis of red blood cells (eosinophils, PB, original magnification × 200; current magnification × 140). (D) Immune rosette (basophil, PB, original magnification × 1,000; current magnification × 700). (E) Immune rosette (immature eosinophil, BM, original magnification × 1,000; current magnification × 700).

with EO-1 by indirect immunofluorescence staining (IF). As can be seen in Table 2, separation of the cells into E rosette-positive (E+) and -negative (E−) fractions did not lead to any clear distribution of the EO-1 cells even though most of the EO-1-positive cells seemed to remain in the E− fraction. Subsequent purification of E− cells into null cells and B cell fractions by selectively removing cells forming immune rosettes with erythrocytes coated with monoclonal antibodies (OKT3, B1, and Mo2 for null cell isolation; OKT3, HNK-1, and Mo2 for B cell isolation) by density centrifugation showed that some EO-1-positive cells were present in both fractions (Table 2). In one instance, we purified B cells from the surgically removed spleen of a patient with idiopathic thrombocytopenic purpura (ITP). The percentage of B1$^+$ cells increased from 23% to 95% after the purification procedure, whereas the number of EO-1-positive cells rose from 4% to 13%. It would thus seem that some B cells do react with EO-1. Most of the normal adherent cells (monocytes) were negative.

Reactivity of EO-1 with human cultured cell line. The reactivity of EO-1 antigen was tested against a panel of cultured human cell lines, and the results obtained from indirect IF are shown in Table 3. The strongest reaction for both the intensity of fluorescence and percentage of positive cells was found with pre-B cell lines (NALM-1, NALM-6) and null cell lines. Three out of seven B cell lines also reacted with EO-1. The percentage of positive cells, however, was smaller and the intensity of fluorescence weaker than for the pre-B cell lines. Two erythroleukemia lines (HEL, K562) and one monoblastic line (THP-1) also reacted with EO-1. In contrast, typical myeloid lines such as HL-60, ML-1, ML-2, and KG-1 were all negative. One monocytic line (U937) and all T cell lines were also unreactive.

Expression of EO-1 in hematopoietic malignancies. The reactivity of EO-1 was studied on different types of leukemic cells. Even though the number of cases studied was small, the results (Table 4) were in agreement with those found on cultured cell lines. All cases of null cell ALL were positive. Most B CLL reacted with EO-1 as well as one case of Burkitt's lymphoma. Three samples of CML-BC were also tested. Two were of the myeloid type and were negative with EO-1. The third sample, which was of the lymphoid type and expressed the common ALL antigen (CALLA), reacted with EO-1. T cell malignancies and AML cases were all negative. One case of basophilic leukemia was highly positive.

Biochemical characterization of the EO-1 antigen. Cell surface antigens of intact platelets were radiolabeled with ^{125}I by the lactoperoxidase technique and detergent solubilized. The results of immunoprecipitation with EO-1 and SDS-PAGE are shown in Fig 3. EO-1 recognized an antigen with an apparent MW of 23 kilodalton (kD) under reducing (Fig 3, lane b) and nonreducing (Fig 3, lane e) conditions.

DISCUSSION

In the present report, we describe the production and characterization of a murine monoclonal antibody, EO-1, raised against peripheral eosinophils from a patient with eosinophilic leukemia. A large number of antibody-producing clones was obtained after fusion, but most of the antibodies that reacted with eosinophils were also positive with neutrophils and/or an autologous B cell line. EO-1 was selected because in the first screening it reacted only with the immunizing cells and mainly eosinophils in PB. In addition it

Classification	No. Positive/No. Tested
Null ALL (CALLA$^+$)	5/5
B CLL (B1$^+$)	5/7
Burkitt's lymphoma (B1$^+$)	1/1
CML-BC lymphoid (CALLA$^+$)	1/1
Myeloid	0/2
AML	0/4
T ALL	0/1
T CLL	0/1
Basophilic leukemia*	1/1

*T3-, Mo1-, B1-, IF10-, J5-negative cells.

was observed that in the BM preparations, EO-1 was negative with mature and immature neutrophils (myelocytes, promyelocytes) and positive with mature and immature eosinophils, basophils, platelets, and some lymphoid cells. It remains to be seen, however, whether all eosinophils express the EO-1 antigen or whether there exist distinct subsets of eosinophils in terms of the EO-1 expression. The selective reactivity of EO-1 with eosinophils is interesting since it is, to our knowledge, the first monoclonal antibody that can distinguish eosinophils from neutrophils and immature myeloid cells. This restricted specificity may be useful for the analysis of differentiation and function of eosinophils.

During these studies on normal blood, we noticed that a small percentage of positive MNC was frequently found. The exact number of positive cells was difficult to assess since platelets, which are present in these preparations, induce a high background and their adherence to monocytes can artificially increase the percentage of apparently reactive cells.[16] However, we tried to determine the nature of these EO-1–positive cells by fractionating MNC preparations into various subsets. No clear distribution of these cells could be obtained because a few EO-1–reactive cells were found in every fraction (E+, E−, null, B, adherent cells). One B cell preparation, however, purified from spleen cells from ITP, contained 13% EO-1–positive cells in a 95% B1–positive cell fraction. These data together with the positive plasmacytoid cells found in the BM samples seem to indicate that some B lineage cells express the EO-1 antigen.

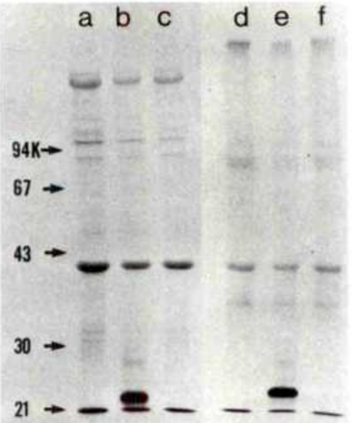

Fig 3. Immunoprecipitation of EO-1 antigen. Platelet membranes were labeled and extracted as described in Materials and Methods. The number shown indicates the mol wt of the protein standards. The EO-1 antigen was analyzed in the absence (lane e) or presence (lane b) of dithiothreitol (DTT). Lanes a and c and lanes d and f show nonspecific bands obtained when unrelated IgGI antibodies were used for control. EO-1 recognized the 23-kD component when electrophoresis was performed under reducing and nonreducing conditions.

Among all the cell lines tested, pre–B cells (NALM-1, NALM-6) and null cells (NALM16, Reh) gave the highest reaction both in intensity and in the reacting number of positive cells. In contrast, typical myeloid lines (HL-60, KG-1, ML-1, ML-2) and all the T cell lines were negative. Similar results were also obtained with fresh malignant cells. Even though the total number of cases available for study was small, we could show that lymphoblastoid malignancies of the null cell type (CALLA$^+$ null cell ALLs) were positive as well as most B cell CLL. These results are interesting because recent data indicate that most null cell ALLs seem to be associated with the B cell lineage.[17,18]

Monoclonal antibodies such as BA-2, DU-ALL-1, and FM8[19–21] recognize pre–B cell–associated antigens and react with B cells, platelets, and polymorphonuclear neutrophils. These antibodies recognize a molecular weight (mol wt) of 24 kilodaltons (kD), which is similar to the mol wt of the EO-1 antigen. However, EO-1 antibody appears to be distinct from these previously described monoclonal antibodies recognizing the 24-kD phenotypic marker of CALLA-positive cells on the basis of specificity. EO-1 does not react with neutrophils. Studies using coprecipitation or antibody blocking will clarify the relationship between the EO-1 antigen and the 24-kD antigen recognized by these monoclonal antibodies.

The reactivity of EO-1 antibody with both eosinophils and basophils is not surprising since both cell types are known to share the same properties, and it has been suggested that they derive from a common progenitor.[22–24] Antibodies recognizing surface determinants shared by platelets and granulocytes, as is the case for EO-1, have also been reported (B37.3, A4).[7,25] The reactivity of EO-1 with B lineage cells was more unexpected. However, there are already numerous examples of unrelated hematopoietic cells bearing similar surface markers. The CALLA antigens, for example, are present on pre–B cells and neutrophils.

Basophilic granulocytes are known to express Fc_ϵ receptors,[26] and more recent reports have established the existence of Fc_ϵ receptors on eosinophils[27] and platelets.[28,29] This cellular distribution of Fc_ϵ receptors seems to correlate with that found for EO-1. However, the evidence that EO-1 does not react with RPMI 8866 (B lymphoblastoid line) and U937, both of which have high levels of Fc_ϵ receptors, and that the inhibition by EO-1 antibody against IgE-rosette binding to eosinophils was not seen (Professor M. Capron, Pasteur Institute, Lille, France, personal communication March 1985) shows that EO-1 does not react with Fc_ϵ receptors, or at least the binding site of the receptor. More experiments will be needed to characterize the relationship between EO-1 and the Fc_ϵ receptors of eosinophils.

In conclusion, we report that murine IgGl monoclonal antibody (EO-1) was produced from mice immunized with purified eosinophils from a patient with eosinophilic leukemia. This antibody precipitated a 23 kD mol wt component. The EO-1 antibody reacted with mature and immature eosinophils, basophils, platelets, and a few lymphoid cells, whereas it did not react with neutrophils and immature myeloid cells. This antibody may be useful for the analysis, isolation, and study of eosinophils and basophils.

ACKNOWLEDGMENT

The authors wish to thank Dr A. Duthu and Dr J.C. Ehrhart (IRSC, France) for their technical advice, and Dr M. Shimoyama (NCCH, Tokyo), Dr T. Tursz (IGR, France), and Dr J. Yodoi (Kyoto University, Japan) for the donation of variable cell lines. The authors are also grateful to Pr M. Capron (Pasteur Institute, Lille, France) for important information.

A Monoclonal Antibody Against an Erythrocyte Ontogenic Antigen Identifies Fetal and Adult Erythroid Progenitors

By P. Edelman, G. Vinci, J.L. Villeval, W. Vainchenker, A. Henri, R. Miglierina, P. Rouger, J. Reviron, J. Breton-Gorius, C. Sureau, and L. Edelman

A murine monoclonal antibody (MoAb) designated FA6-152 has been obtained by immunizing mice with fetal erythrocytes. This antibody agglutinates fetal but not adult erythrocytes. Among blood cells, this antibody bound to both adult and fetal monocytes, platelets, and reticulocytes, but did not react with lymphocytes and granulocytes. Fluorescent labeling of marrow cells and of in vitro BFU-E, CFU-GM, and CFU-MK-derived colonies has shown that the antigen defined by FA6-152 MoAb was absent from the granulocytic precursors and was detected on the megakaryocytic lineage at a later stage of differentiation than the platelet-specific markers. In contrast, the antigen appeared as a very early marker of the erythroid differentiation since all erythroblasts, including proerythroblasts, were labeled even before the expression of glycophorin A. Cells from adult marrow and fetal liver were sorted with the FA6-152 MoAb and studied by electron microscopy and cell culture. The negative fraction contained granulocytic, monocytic, and megakaryocytic precursors, whereas the positive fraction was devoid of these precursors and contained monocytes, erythroblasts at all stages of maturation, and a homogenous population of blasts. Cultures have shown that the only hematopoietic progenitors present in this positive fraction were CFU-E and some BFU-E. The antigenic density was related to the differentiation stage of the erythroid progenitors. In conclusion, this antibody is similar to the previously described 5F1 MoAb (Bernstein and Andrews, *J Immunol* 128:876, 1982; and Andrews et al, *Blood* 62:124, 1983) and provides a useful probe for studies leading to improved understanding of normal and malignant erythroid differentiation.

NUMEROUS ONTOGENIC changes are observed in the biology of the erythrocyte. The most striking ontogenic event concerns hemoglobin switching. Nevertheless, blood group antigens also exhibit numerous important developmental changes. The antigens of the A, B, and H systems are slightly expressed at the third week of the intrautero life.[1] As early as the 40th day of fetal life, the antigens of the ABH, Duffy, JK, and rhesus blood group systems are fully expressed on the surface of the erythrocytes. However, fetal erythrocytes differ from adult erythrocytes by the arborized pattern of the carbohydrate structure of their glycolipids and glycoproteins.[2,3] This difference is now considered to be the basis of i-to-I antigen conversion.[4-6] The i/I expression during adult erythroid differentiation mimics the ontogenic changes. Indeed, i antigen is preferentially detected on immature erythroblasts whereas increasing expression of I antigen is observed during terminal erythroid differentiation.[7,8] However, at the level of adult erythroid progenitors, ie, CFU-E and BFU-E, I antigen predominates over i antigen.[9] Therefore, ontogenic erythrocyte antigens can be helpful markers in studies of cellular differentiation and may be also useful for identification of fetal erythrocytes in maternal blood during pregnancy.

Our purpose was to define new ontogenic erythrocyte antigens with monoclonal antibody (MoAb) obtained by immunizing mice with fetal erythrocytes and to investigate the expression of such antigens during the erythroid differentiation.

MATERIALS AND METHODS

Immunization protocol. Balb/c mice (IFFA Credo, Lyon, France) were immunized using a suspension of 20-week-old fetal red cells (RBC). These heparinized RBC were washed three times in saline (0.15 mol/L NaCl), and 20 × 10^6 cells were injected on day 1 and day 18 intraperitoneally. Three days after the last immunization, spleen cells were prepared, and fusion was performed as previously reported.[10,11]

Supernatant screening. Culture supernatants were tested by a hemagglutination test using papain- and bromelain-treated adult and fetal RBC. The subsequent reactions were performed in microtubes by mixing 20 μL of the aforementioned RBC suspension and 20 μL of supernatants. The mixture was incubated for 30 minutes at 37 °C and then read with a microscope for agglutination.

Cloning. The cells secreting an antibody of interest were cloned by the limiting dilution technique. The cells taken from one well were brought into suspension with a feeder layer (thymocytes from Balb/c mice) and distributed in 96-well plates so as to obtain an average cell density of 5, 1, and 0.5 cells per well. Two successive clonings were performed. For further studies, the culture supernatant or ascitic fluid was used as sources for the MoAb.

Characterization. Identification of the MoAb was carried out using a panel of adult different erythrocyte phenotypes; agglutination tests were performed by adding one volume of a 10%-treated RBC suspension to an equal volume of culture supernatant or ascitic fluid. Both macroscopic and microscopic readings were made after one hour of incubation at 22 °C. Immunoglobulin class and subclass of the monclonal antibody were determined by immunodiffusion of ascitic fluid against subclass-specific antiimmunoglobulin antisera (Meloy Laboratories, Springfield, Va).

Samples. Adult RBC of known phenotype or fetal blood samples obtained from therapeutic abortion or fetoscopy for antenatal diagnosis were used. The blood cells were collected into heparin, washed three times in saline (0.15 mol/L NaCl), mixed in a glycerol (17.5%), mannitol (1.44%), and NaCl (0.32%) solution, and frozen in liquid nitrogen. Adult RBC with rare phenotypes were thawed and bromelin treated. Liver and thymus cells were removed one hour after delivery from therapeutic abortion, placed into Dulbecco's medium containing 10% foetal calf serum, and subsequently frozen.•

Isolation of the cells. Normal mononuclear cells from heparinized peripheral blood or bone marrow were separated by Ficoll-metrizoate gradient density centrifugation (Lymphoprep, Nyegaard, Sweden; d:1077).[12] Adherent and nonadherent peripheral blood mononuclear cells were separated by a two-hour adherence on plastic Petri dishes. The granulocytes from the pellet of the Ficoll-metrizoate gradient density centrifugation were separated from RBC by dextran sedimentation. Platelets were obtained from platelet-rich plasma. Reticulocytes were separated on a phthalate oil density gradient[13] from a patient with autoimmune hemolytic anemia.

Bone marrow cells were isolated from aspirates obtained from donors for bone marrow transplantation procedures. Nucleated cells were either obtained from a buffy coat preparation or after Ficoll-metrizoate gradient density centrifugation. Blood cells from 40 patients with acute leukemia were also tested.

Cell lines. Five lymphoblastoid cell lines, five Burkitt cell lines (including Daudi and P3HR1), three T cell lines (Jurkatt, Molt 4, HSB 2), HL 60 (a promyelocytic cell line), U 937 (a monoblastic cell line), two erythroleukemic cell lines (HEL and K 562), and two hybrid cell lines[14] between K 562 and P3HR1 and K 562 and DAUDI (Putko and Dutko, respectively) were investigated. In addition, HL 60 and U 937 were studied before and after 12-0-tetradecanoyl phorbol-13-acetate (TPA) and 1.23 dihydroxy-vitamin D_3 induction. All cell lines were cultured in RPMI medium (Boehringer, Mannheim, West Germany) with 10% fetal calf serum (Boehringer).

Fluorescent labeling on separated cells. Supernatant or ascitic fluid was used undiluted or 100-fold diluted in sterile phosphate-buffered saline (PBS), respectively. Unfixed cells were incubated at 4 °C for 30 minutes with the antibody. After three washes in cold PBS, cells were incubated with a 10^{-2}-diluted fluorescein-conjugated goat $F(ab')_2$ fragment directed against mouse IgGs (Cappel Laboratories, Cochranville, Pa) for 30 additional minutes, washed, smeared, and fixed for one minute with pure methanol. They were examined under a Zeiss episcope equipped with appropriate filters for fluorescein and rhodamine and for phase contrast.

Cell sorting. Fluorocytometric analysis and cell sorting were performed with an Ortho 50 H cytofluorograf (Ortho Diagnostics, Westwood, Mass) as previously described.[9] Light-density marrow cells from bone marrow transplantation donors were frozen, thawed just before the cell sorting experiment, labeled with an antibody by an indirect fluorescent technique (see the previous section), and kept in ice until cell sorting. Collected cells from the two fractions were used for clonogenic assays, cytocentrifuge preparations, and electron microscopic (EM) studies (see the following section).

The cytocentrifuge slides were stained by the May-Grunwald-Giemsa technique or labeled by an indirect fluorescent technique after methanol fixation with rabbit polyclonal antibodies against myeloperoxidase[15] or von Willebrand Factor (vWF) (Dakopatts, Copenhagen, Denmark). In one experiment, adult and fetal RBC were mixed in two different percentages (10% fetal and 1% fetal) and subsequently sorted. Frankly positive RBC were obtained and allowed to settle onto polylysine-coated slides.[16] Fluorescent labeling with a rabbit antihuman γ-globin chain[17] was subsequently performed after ethanol–glacial acetic acid fixation.

Clonogeneic assays. The clonogeneic assays for BFU-E, CFU-E, CFU-GM, and CFU-MK were performed by the plasma clot technique.[18] The stimulating factors were either phytohemagglutinin leukocyte-conditioned medium (PHA-LCM) for CFU-MK and CFU-GM colony growth and PHA-LCM plus 1 IU/mL porcine erythropoietin (Epo) (CNTS, Paris) for CFU-E and BFU-E. These cultures were performed with two goals in mind.

First, the cultures allow the preparation of enriched populations of erythroblasts, granulocytes-monocytes, and megakaryocytes from BFU-E, CFU-GM, and CFU-MK cultures, respectively. Studies at day 6 or 7 of the cultures permit the characterization of populations of immature erythroblasts, granulocytes, or megakaryocytes, whereas similar studies at day 13 permit the investigation of mature cells. Fluorescent labeling with FA6-152 MoAb was performed directly on the Petri dish as previously described.[19]

Second, the cultures have permitted us to study the types of progenitors contained in the two fractions collected with the cell sorter. All cultures were performed in the presence of PHA-LCM and Epo. Cultures were studied at day 7 for CFU-E, at day 12 for CFU-GM, mature BFU-E, and CFU-MK, and at day 16 for primitive BFU-E. They were investigated by fluorescent labeling with three MoAbs, ie, LICR LON R10 (anti-glycophorin A),[22] C 17 (antiplatelet glycoprotein IIIa),[21] and 80 H 5 (anti-SSEA-1 antigen),[22] specific for the erythroid, megakaryocytic, and granulocytic-monocytic lineages, respectively. Each dish was entirely scanned.

Ultrastructural studies. The two fractions of cells (positive and negative) collected with the cell sorter were fixed by 1.25% glutaraldehyde in Gey's basic salts[23] for ten minutes, washed and incubated in 2 mg/mL diaminobenzidine medium (Sigma Chemical Co, St Louis).[24] The cells were then washed, postfixed, dehydrated, and embedded in epon. Thin sections were examined with a Philips electron microscope. This technique permits monitoring of different peroxidase activities, ie, myeloperoxidase, platelet peroxidase, and the peroxidase activity of hemoglobin.[25] Cells were also studied by the immunogold technique with the FA6-152 MoAb.[25]

RESULTS

Reactivity with erythrocytes. Two weeks after fusion, 320 wells out of 1,024 contained hybrid cells. Twelve were secreting antibodies against adult and fetal human RBC. Only one well, ie, FA6-152, produced an antibody that agglutinated only fetal RBC. The supernatant was tested against a panel of 69 adult RBC typed in the ABO, rhesus, Kell, Duffy, Kidd, P, MNSs, Lutheran, Colton, Cartwright, Xg, Sid, and Dombrock systems, a panel of 16, 18, 20, 22, 24, 27, 30, and 32-week-old fetal RBC and a panel of 23 cord blood RBC. Only fetal RBC up to 32 weeks old were agglutinated by the FA6-152 MoAb (Table 1). This antibody was characterized as an IgG1 antibody. Even adult RBC with a rare phenotype such as TJa-, Cartwright –, Gerbich –, Vel –, Colton –, kpb –, U –, i, PK, Bombay, and Celano were not agglutinated by the MoAb.

By fluorescent technique, adult erythrocytes were unlabeled, but some adult reticulocytes were faintly stained. About 50% of fetal RBC were labeled, whereas 10% to 20% cord blood RBC were stained. Cell sorting of artificial mixtures of fetal and adult erythrocytes was performed. For an initial mixture of 10% fetal RBC, 95% fetal RBC (labeled by an anti–γ-globin chain) were present in the positive fraction whereas for a mixture containing 1% fetal RBC, 60% fetal RBC were present in the positive fraction.

Reactivity with other blood cells. In the adult, 30% to 40% of the blood mononuclear cells were labeled. These cells were larger than the others and exhibited some granulation in phase-contrast microscopy. More than 90% of the adherent cells were stained, whereas less than 1% were labeled in the nonadherent population. Granulocytes were unlabeled. All the platelets from several donors were labeled by the antibody in a double fluorescent procedure using a polyclonal

antifactor vWF to identify the platelets. EM studies by the immunogold technique have clearly confirmed that all platelets and monocytes bind the antibody whereas lymphocytes and granulocytes were devoid of the antigen.

Reactivity with hematopoietic precursors—Labeling of blood cell precursors. Ten percent to 35% of the marrow cells were labeled by the antibody. When examined by phase contrast, they consisted of erythroblasts at all stages of maturation, megakaryocytes, and monocytes. Granulocytic precursors were unlabeled. Similar results were obtained at the EM level. To determine more precisely the stage of maturation of the cells labeled by FA6-152, fluorescent labeling was performed on BFU-E–, CFU-GM–, and CFU-MK–derived colonies. All the erythroblasts composing a BFU-E colony were stained by the antibody at the early or late days of culture. Blood BFU-E colonies were stained as early as day 5 of culture. In similar experiments, MoAb directed against glycophorin A labeled the BFU-E–derived colonies, but not before day 8 or 9 of culture. Pure granulocytic colonies remained entirely unlabeled by the MoAb. Only large macrophages were intensively stained in the CFU-GM assay. Large mature megakaryocytes shedding platelets were intensively stained by the FA6-152 MoAb. At day 7 of culture when a large number of immature megakaryocytes were present, only 60% of the megakaryocyte labeled by antifactor vWF were reactive with FA6-152 MoAb. In particular, small megakaryocyte precursors were weakly labeled or unstained. Results were similar in colonies cultured from fetal progenitors, but with a more intense staining on fetal erythroblasts and megakaryocytes than on their adult counterparts.

Table 2. Reactivity of FA6-152 With Several Hematopoietic Cell Lines

	Percentage
Lymphoblastoid (five cell lines)	—
Burkitt's lymphoma (five cell lines)	—
T-ALL (three cell lines)	—
U937	3.5 ± 2
TPA induced	2 ± 1
Dehydroxy-vitamin D_3	3.5 ± 2
HL 60	—
TPA induced	—
HEL	75 ± 10
K 562	2 ± 2
Putko (hybrid between K 562 and P3 HR-1)	>90
Dutko (hybrid between K 562 and Daudi)	>90

Abbreviation: T-ALL, T cell acute lymphocytic leukemia.

Hematopoietic cell lines and leukemic cell. Among the cell lines tested, only HEL, Putko, and Dutko expressed the antigen defined by FA6-152 on a majority of cells. This antigen was also detected on a minority of K 562 and U 937 cells. (Table 2) Fifteen cases of acute lymphoblastic leukemia were investigated, and all cells were negative. In 25 cases of acute myeloid leukemia, only the cases containing a mature or immature monocytic component (M_4 and M_5) according to the French-American-British (FAB) classification[26] were stained; M_1, M_2, and M_3 cases were always negative.

Morphologic features of the marrow cell fraction collected by cell sorting. These experiments were performed on bone marrow aspirates obtained from normal donors for bone marrow transplantation. These samples were heavily

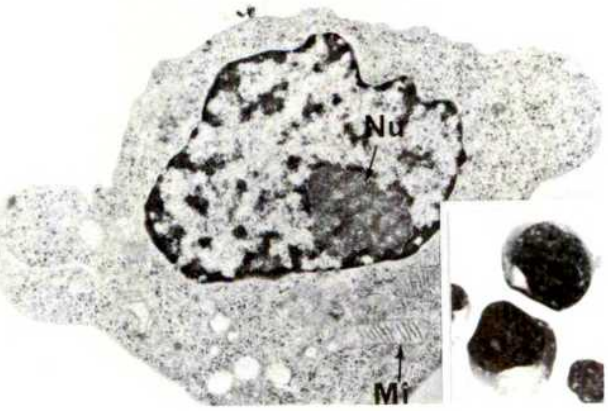

Fig 1. Blast cells present in the positive fraction. EM examination of a blast cell present in the positive fraction. EM shows that this cell cannot be identified since no peroxidase activity can be detected. The nucleus contains mainly euchromatin: the heterochromatin is present along the nuclear membrane and surrounds the nucleolus (Nu). The cell membrane is smooth, without pseudopods, but two symetric cytoplasmic blebs are seen. The cytoplasm contains rare cisternae of endoplasmic reticulum but numerous polysomes: the mitochrondria (Mi) are large and the Golgi apparatus exhibits a number of vesicles. Several vacuoles are present, and an annulate membrane can be observed bottom right. Note the absence of rhopheocytosis and ferritin molecules (original magnification × 5,200; current magnification × 4,472). (Inset) May-Grunwald-Giemsa staining of two blast cells present in the positive fraction. The blast cells are large with a basophilic cytoplasm. The nucleus is slightly indented and contains a large nucleolus.

	Negative	65	115 ± 11	37	134 ± 23	89.5	ND		126 ± 42	91	26 ± 5	93
2	Positive I	34	235 ± 33	53.5	3 ± 2	1.1	3 ± 2	2.5	29 ± 15	4.8	0	0
	Negative	63	79 ± 10	33	148 ± 35	93	59 ± 9	92.5	308 ± 62	93	24 ± 8	80

Abbreviations: CF, cell fraction; ND, not determined.

*The percentage is calculated as follows: CFU/10^5 sorted cells × percentage of viable cells in fraction/(CFU/10^5 unsorted cells). In both cases, bone marrow from a marrow donor for marrow transplantation was separated by Ficoll density centrifugation, stored frozen with 10% dimethylsulfoxide in liquid nitrogen, and thawed for sorting.

The positive fraction contained only bright fluorescent cells, whereas the negative fraction contained the clear negative fraction and the cells collected in the shoulder of fluorescence (Fig 2).

contaminated by cells of blood origin, thus explaining the high percentage of lymphocytes and monocytes.

Thirty percent to 40% of the examined cells were labeled. This positive fraction comprised 79% to 85% monocytes; 1% to 2% additional immature monocytes were also present. The positive fraction included all the erythroblasts and proerythroblasts. No identifiable myeloid precursors were present. This fraction also included 3% to 8% blast cells that were not labeled by polyclonal antibodies against factor vWF or myeloperoxidase. These cells contained carbonic anhydrase I, another early erythroid marker.[27]

The two fractions collected were subsequently examined by EM. The negative fraction contained all the neutrophil, eosinophil, and basophil precursors. Promonocytes synthesizing myeloperoxidase (ie, presence of a peroxidase activity in the Golgi apparatus and the endoplasmic reticulum) or having terminated this synthesis and rare promegakaryoblasts identified by the typical platelet peroxidase were also present. In the positive fraction, the majority of cells examined were monocytes that were rather mature since no synthesis of myeloperoxidase was detected. Proerythroblasts were clearly identified by the presence of ferritin in rhopheocytosis vesicles and in small clusters in the cytoplasm. A homogenous population of blast cells without any cytochemical or morphologic criteria for identification were present (Fig 1). They differed from the blast cells of the negative fraction by their large size, abundant cytoplasm rich in free ribosomes, mitochondria of large size, and granules located in the Golgi apparatus zone. The slightly indented nucleus contained a large and multiple nucleolus.

Hematopoietic progenitor content of the adult bone marrow cell fractions collected by cell sorting. After indirect fluorescent labeling with FA6-152 MoAb, marrow cells were analyzed and sorted on the basis of fluorescent intensity (Tables 3 and 4). A typical histogram is shown in Fig 2. It was characterized by a clear population of negative cells and a marked shoulder preceding the FA6-152 bright cells. We could determine that this shoulder was contaminated by 2% to 10% negative cells when control IgG1-labeled cells were studied. In contrast, the FA6-152 bright cells contained less than 0.05% negative cells.

In two experiments, the positive fraction (positive I) only contained the FA6-152 bright cells, whereas the negative fraction also included the shoulder of fluorescence (Fig 2A). Results are shown in Table 3. More than 50% of the CFU-Es were grown from the positive I fraction, largely in the absence of all the other hematopoietic progenitors. The CFU-Es giving rise to eight to 32 cell colonies were predominantly found in this fraction, whereas most of the CFU-Es giving rise to 32 or more cells were detected in the negative fraction containing both truly negative cells and cells expressing a low antigenic density of the antigen (Fig 3).

In two additional experiments (Table 4), FA6-152 bright cells and a part (experiment 3) or all (experiment 4) of the cells in the shoulder of fluorescence and therefore corresponding to cells exhibiting a low antigenic density were included in the positive fraction (positive II fraction). Most or all CFU-Es and a part of the day 12 BFU-E were grown from the positive II fraction, whereas all the other hematopoietic progenitors including the day 16 BFU-E were absent from this fraction. The positive sorting of cells expressing a very low antigenic density in only experiment 4 may explain the differences between experiments 3 and 4.

Finally, cells with a high antigenic density (positive I) were separated from the cells with a low antigenic density (intermediate) (Table 4, experiment 5, Fig 2B). The positive I fraction contained only a part of the CFU-Es, whereas the intermediate fraction included the other CFU-Es and a

Table 4. Progenitor Cell Growth From the Two Fractions Collected by Cell Sorting From Adult Bone Marrow

Experiment No.	CF	Percentage of CF	CFU-E		Day 12 BFU-E		Day 16 BFU-E		CFU-GM		CFU-MK	
			per 10^5 CF	Percentage*	per 10^5 CF	Percentage*	per 10^5 CF	Percentage*	per 10^5 CF	Percentage*	per 10^5 CF	Percentage*
3	Positive II	34	402 ± 43	89	74 ± 12	29.8	0	0	91 ± 18	10.5	ND

	Intermediate	5	1,100 ± 185	36.3	1,140 ± 263	69.7	60 ± 32	7.4	40 ± 15	1	0	0

*The percentage was calculated as in Table 3.

In contrast to Table 3, the positive fraction also contained a part of the shoulder of the fluorescent histogram (experiment 3), or the whole shoulder (Experiment 4). In experiment 5, the intermediate *fraction only contained the shoulder, whereas the positive fraction (see experiment 2) only contained the FA6-152 bright cells.

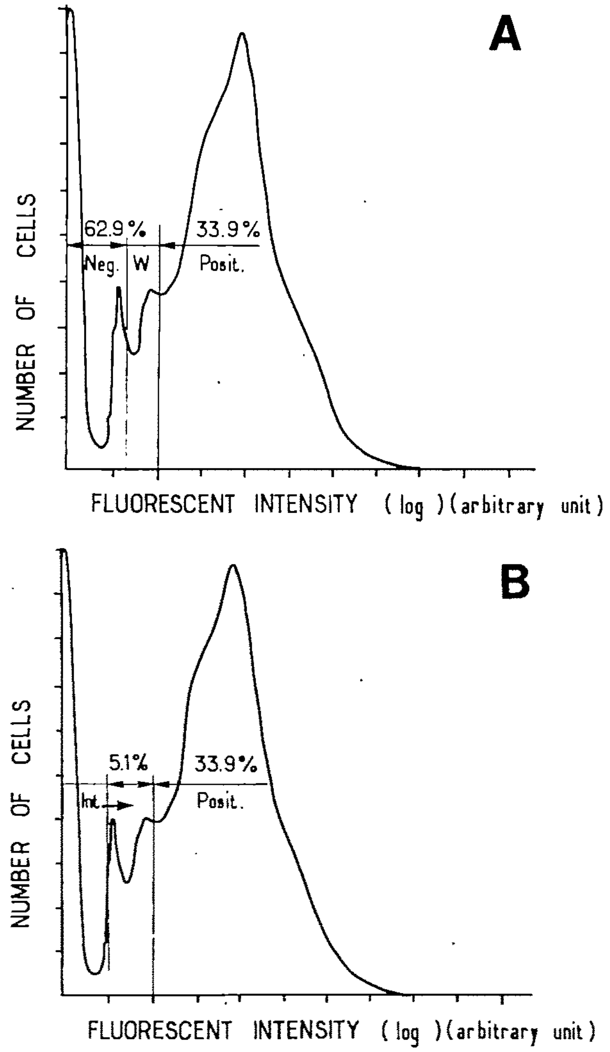

Fig 2. Fluorescence histograms of the bone marrow cells labeled with FA6-152 MoAb. The histogram was characterized by clearly negative and positive cells. However, a marked shoulder in the curve was constantly observed. (A) In experiments 1 and 2, the negative fraction contained a part of the cells located at the shoulder of the fluorescent intensity. The positive fraction contained only bright fluorescent cells. A window of cells between the two fractions was discarded. (B) In experiment 5 (identical bone marrow cells as in experiment 2), the positive fraction was collected as in (A). The other fraction, called intermediate, contained all the cells located at the shoulder of the fluorescence curve.

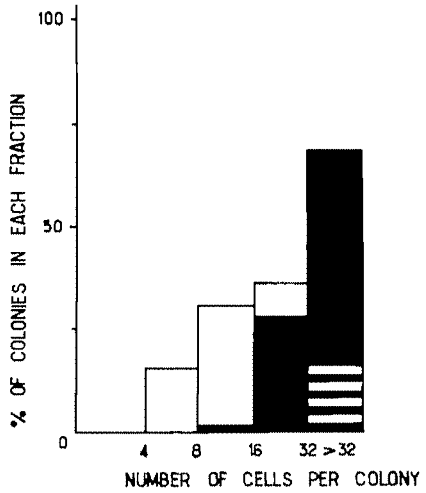

Fig 3. Size of the day 7 erythroid colonies present in the positive and negative fraction separated as in Fig 1A. This figure illustrates the size of the colonies in the positive and negative fraction. The colonies were classified in four classes. The four- to eight-cell colonies were not included in the quantitation of CFU-Es (Tables 2 to 6).

part of day 12 BFU-Es. The other hematopoietic progenitors were absent from these two fractions.

To demonstrate that the absence of BFU-E and CFU-GM in the positive fraction collected was not the consequence of the high concentration of monocytes as previously described,[28] we studied the positive fraction after adherence (Table 5). No significant differences in the number of colonies were observed. In addition, the positive and negative fractions were remixed after sorting; the number of CFU-E and CFU-GM observed did not markedly differ from the sum of the number of colonies found in the two fractions, thereby indicating that no inhibitory cells were present in the two fractions.

Hematopoietic progenitor content of the fetal liver cell fractions collected by cell sorting. Concerning experiments in Table 1 on the adult marrow, we collected the bright stained cells as the positive fraction and the other as the negative (Table 6). The positive fraction contained more than 90% erythroblasts, 72.5% of the CFU-E, and 34% of the mature BFU-E; in contrast, the negative fraction contained most if not all the primitive BFU-E, CFU-GM, and CFU-MK.

DISCUSSION

In this report, we have described a MoAb obtained by immunizing mice with human fetal erythrocytes. The purpose of this immunization was to detect ontogenic antigens present on fetal erythrocytes but not on adult erythrocytes. The antigen detected by FA6-152 MoAb has this characteristic. Therefore, we have extensively studied the expression of this antigen on adult and fetal hematopoietic cells including

Table 5. Adherence and Mixing Experiments

	CFU-E	CFU-GM	BFU-E
Positive fraction			
Before adherence	75.5 ± 5	10 ± 2	2 ± 1
After adherence	65 ± 8	8 ± 5	3 ± 2
Negative fraction	41.5 ± 10	159 ± 22	
Positive fraction (before adherence) + negative fraction	140 ± 25	177 ± 25	

Cells from experiment 2 were grown in triplicate at 3 × 10^4 cells per mL for each fraction. The positive fraction was studied before and after one-hour adherence to plastic. A total of 3 × 10^4 positive and 3 × 10^4 negative cells were also mixed.

Table 6. Cell Sorting of Fetal Liver Cells

	Day 5 CFU-E		Day 8 BFU-E		Day 12 BFU-E		Day 12 CFU-GM		Day 12 CFU-MK	
Percentage	per 10^5 CF	Percentage	per 10^5 CF	Percentage	per 10^5 CF	Percentage	per 10^5 CF	Percentage	per 10^5 CF	Percentage
Positive fraction 60%	372 ± 44	40.7	212 ± 28	32.26	182 ± 24	7.8	15 ± 4	4.6	0	0
Negative fraction (40%)	210 ± 18	26.7	620 ± 75	62.8	2,933 ± 340	83.8	303 ± 27	93.2	62.5 ± 24	78.1

Liver cells from a 20-week-old fetus were frozen, then thawed for sorting experiments. Cells were labeled by FA6-152 and then separated as in Fig. 2A in two fractions and cultured. Cultures were performed in triplicate at 3 × 10^4 cells per mL. Results are expressed per 10^5 cells in each fraction.

progenitors and on continuous cell lines. On adult peripheral blood, this antigen was not detected on erythrocytes. Some reticulocytes, most if not all monocytes, and all platelets bore the antigenic determinant defined by FA6-152. It was not detected on granulocytes and lymphocytes. A similar cellular reactivity was found in four (12- to 20-week-old) fetuses with the exception of a reactivity on erythrocytes. Agglutination of neonatal RBC was not observed, whereas fluorescent labeling was detected in 10% to 20% of the neonatal RBC. In addition, the antigen defined by FA6-152 is not specific for the hematopoietic tissue since it was detected on frozen sections from several adult or fetal organs in the perivascular spaces of the vessels. Reactivity was therefore detected in the small intestine, kidney, liver, and thyroid.

The antigen could not be biochemically characterized by immunoprecipitation and Western blotting on SDS-PAGE (Cartron, Centre National de Transfusion, Paris, 1985). The absence of destruction of the antigen by several proteolytic enzymes such as trypsin and pronase suggests that this antigen is a glycolipid or a carbohydrate structure associated with a glycolipid. MoAbs against the carbohydrate structure have permitted a characterization of such ontogenic ubiquitous antigens as the SSEA-1 antigen, which are also differentiation markers.[29]

Bone marrow, fetal liver hematopoietic precursors and also their counterparts obtained in vitro from BFU-E, CFU-GM, and CFU-MK differentiation were investigated. In the adult as in the fetus, FA6-152 MoAb labeled all erythroblasts including normoblasts. We could demonstrate that the antigen identified by the FA6-152 MoAb was synthesized at an earlier stage of erythroid differentiation than glycophorin A since the colonies derived from blood BFU-E were labeled as early as day 5, whereas a MoAb against glycophorin A did not stain the colonies before day 8. In contrast, the present antigen was expressed in megakaryocytic differentiation later or at the same time as the specific platelet proteins.[19,30] In addition, investigation by EM of the positive and negative marrow cell fractions obtained by cell sorting as well as unsorted marrow cells has shown that promonocytes were devoid of the antigen identified by the FA6 152-MoAb, thereby indicating that this antigen is also a late marker of the monocyte differentiation. All these results are summarized in Fig 4. Considering the results observed in the adult, the reactivity of FA6-152 is in many ways similar to two previously described MoAbs, ie, 5F1[31] and 20/3.[32] Both of them are IgM MoAb obtained by immunization of mice with acute myelomonocytic leukemic cells or normal peripheral mononuclear cells. The reactivity of 5F1 and 20/3 on fetal cells has not been published. We recently found that 5F1 also binds to some fetal erythrocytes.

We investigated the reactivity of FA6-152 with hematopoietic progenitors. It clearly appeared that FA6-152 stained only the erythroid progenitors. Interestingly, there was a marked increase in the antigenic density from the BFU-E to the CFU-E in the adult as in the fetus. The primitive BFU-E[33] did not bear the antigen identified by FA6-152, whereas the mature BFU-E[33] expressed a low density of this antigen. Mature BFU-E and a large part of the CFU-E were found in the 5% marrow cells whose fluorescent intensity was just located at the threshold of positivity. In contrast, the CFU-E that gave rise to small-sized colonies were all included in the intensively stained fraction. Therefore, the

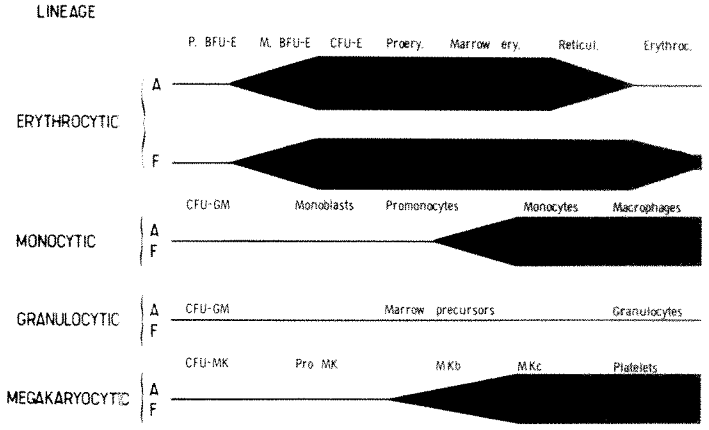

Fig 4. A schematic representation of the expression of FA6-152 on adult and fetal hematopoietic cells. Abbreviations: A, adult; F, fetus.

presence of the antigen defined by FA6-152 on the erythroid progenitors was the reflection of their differentiation stage defining three or four classes of progenitors as previously described when using other differentiation markers such as their hormonal regulation, the size of the colonies, and the in vitro time course of the colonies.[33] Primitive BFU-E whose differentiation depends upon another factor besides Epo were devoid of the antigen defined by FA6-152; mature BFU-E[33] that have acquired an Epo sensitivity bore very low amounts of the antigen, and CFU-E were heterogenous with respect to their antigenic density. The majority of the colonies composed of 32 or more erythroblasts were derived from a progenitor with an antigenic density comparable to the mature BFU-E. In contrast, the colonies composed of eight (or four) to 32 erythroblasts were derived from a progenitor with a high antigenic density. Several authors have pointed out that the compartment of human CFU-E is heterogenous. In particular, the CFU-E that gave rise to small colonies with a peak at day 4 to 5 of culture[34] were highly Epo sensitive[35,36]; they appeared similar to the erythroid progenitor that is intensively stained by the FA6-152 MoAb. EM examination has shown the presence of a homogenous population of undifferentiated cells in the positive fraction. These cells stand as possible candidates for human CFU-E. They have morphologic features similar to the murine CFU-E isolated by a density gradient.[37] In addition, they express another early erythroid marker, ie, carbonic anhydrase I.[27]

Most previously described MoAbs recognized either hematopoietic progenitors, irrespective of their cell lineages,[9,38-43] or CFU-GM.[20,38,44-46] Only one recently described MoAb, ie, EP-1[47] appears specific to the erythroid lineage from the erythroid progenitors (BFU-E and CFU-E) to the erythroblasts. The 5F1 MoAb has also been described as recognizing CFU-E.[38] Therefore, some antibody competition was performed between 5F1 and FA6-152 MoAbs. Only a partial inhibition between the two MoAbs was observed, suggesting that they recognize different epitopes of the same antigen.

In conclusion, we have described a MoAb that recognizes an ontogenic antigen. This antigen is not detected on the surface of adult erythrocytes, but is present on their fetal counterparts. It is present on nucleated erythroblasts and the megakaryocytic and monocytic series. However, for these two hematopoietic cell lineages, FA6-152 is a late marker of differentiation; in contrast, the antigen recognized by FA6-152 is expressed on mature BFU-E with an antigenic density increasing until day 5 CFU-E. This antibody will permit an improved understanding of both normal and leukemic erythroid differentiation.

ACKNOWLEDGMENT

The authors wish to thank Dr P.A.W. EDWARDS (Ludwig Institute for Cancer Research, Sutton, Surrey WK) for providing LICR LON R 10, Dr P. Tetteroo (Central Laboratory of the Netherlands, Red Cross Blood Transfusion Service, Amsterdam) for C 17, Dr P. Mannoni (Faculty of Medicine, University of Alberta, Canada) for 80H5, and Dr I.D. Bernstein (Fred Hutchinson Cancer Research Center, Seattle) for 5F1. We thank J. Guichard and P. Veysseyre for excellent technical assistance and A.M. Dulac for typing the manuscript.

Biosynthesis and Secretion of Factor VII, Protein C, Protein S, and the Protein C Inhibitor From a Human Hepatoma Cell Line

By Daryl S. Fair and Richard A. Marlar

Using specific radioimmunoassays, 8 day cultures of Hep G2 cells were shown to contain in their supernatants 16, 74, and 828 ng/mL and in their cell lysates, 8, 55, and 48 ng/2 × 10^8 cells of factor VII, protein C, and protein S, respectively. These proteins and the protein C inhibitor were functionally active, and each of these activities was neutralized by their respective polyclonal antibodies. Although vitamin K had a modest effect, warfarin decreased the activity of secreted factor VII, protein C, and protein S by 50% to 90%. Protein C and protein S antigens were reduced three- to fourfold by warfarin. The protein C inhibitor antigen and activity were unaffected by vitamin K or warfarin treatment. Intrinsic labeling and immunoprecipitation indicated that factor VII, protein S, and the protein C inhibitor were secreted as 52,000, 77,000, and 58,000 molecular weight (mol wt) proteins, respectively. Protein C was secreted as a single-chain protein of about 65,000 mol wt, indicating that all of the vitamin K-dependent proteins are translated and secreted as single-chain molecules. Each of the four proteins studied represented their plasma protein counterparts structurally, functionally, and immunochemically. Thus, all of the known soluble components of the protein C pathway are produced by liver parenchymal cells.

VITAMIN K-DEPENDENT proteins are characterized as glycoproteins that are carboxylated at selected glutamic acid residues (gla) by a posttranslational process involving at least two enzymes and vitamin K.[1,2] Warfarin is an antagonist of vitamin K and inhibits this reaction. The gla residues permit the binding of calcium, which induces a conformational change in the protein and mediates its binding to negatively charged phospholipid surfaces. Most, but not all of these proteins, contain a second unique alteration, namely, the presence of a β-hydroxyaspartic acid.[3,4] The function of this modified residue is unknown.

Factor VII, a single-chain 50,000-molecular weight (mol wt) protein containing nine gla residues,[5,6] initiates coagulation when associated with the lipophilic, nonenzymatic cofactor, tissue factor.[7] It is an active zymogen exhibiting 0.8% to 4% of the activity of its activated serine protease form.[6,8,9] In contrast, protein C, a two-chain 62,000-mol wt molecule containing 11 gla and one β-hydroxyaspartic acid residues is an inactive zymogen.[3,4,10,11] However, once activated by thrombin-thrombomodulin, it is a potent anticoagulant serine protease that inactivates factors Va and VIIIa.[12] The function of activated protein C is enhanced in the presence of another vitamin K-dependent molecule, protein S.[13] This single-chain 75,000-mol wt protein, which contains nine to ten gla residues and one β-hydroxyaspartic acid residue has been proposed to function as a nonenzymatic cofactor for activated protein C.[3,4,13-15] Inhibition of activated protein C is by a novel, recently isolated 57,000-mol wt single-chain plasma protein that neutralizes activated protein C by forming a stable 1:1 molar complex.[16,17]

The liver has been shown to be the primary source of plasma proteins including those of the coagulation and fibrinolytic systems, although this conclusion was based on indirect evidence of earlier studies.[18,19] With the advent of animal organ perfusion and cell culture, activity studies were used as evidence for the liver and the parenchymal cell as the principal site of synthesis of most of the plasma proteins.[20-25] Because the human molecules have been isolated and well characterized, the human hepatoma cell line, Hep G2, has been used to assign the site of synthesis of most of the zymogens and inhibitors of the coagulation and fibrinolytic systems to the hepatocyte.[26-30] Factor VII has been shown to be produced by rodent liver cells.[21,22,31-33] It has been assumed that most of the components of the protein C system (protein C and protein S) are produced by the liver based on clinical studies.[34,35] We used the Hep G2 cell line to demonstrate that factor VII, protein C, protein S, and the protein C inhibitor are synthesized by hepatocytes and that each of the molecules represents their plasma protein counterparts structurally, immunochemically, and functionally. In addition, we demonstrate that protein C is secreted as a single-chain molecule, analogous to factor X.[30]

MATERIALS AND METHODS

Cell culture. The human hepatoma cell line, Hep G2, was obtained from Drs Barbara B. Knowles and David A. Aden of the Wistar Institute, Philadelphia. The cells were maintained in T-75 culture flasks containing Eagle's modified medium supplemented with 10% heat-inactivated fetal calf serum (FCS) by passage of at least 10^6 cells per flask as previously described.[30] Cells were occasionally cultured for four to five days in the absence of serum to test the effects of 1 μg/mL of a warfarin derivative, 3(α-acetonyl benyl)-4-hydroxycoumarin (Sigma Chemical Co, St Louis) or 10 μg/mL of vitamin K (Aqua Mephyton, Merck, Sharp and Dohme, West Point, Pa) as described previously.[30]

Proteins. Factor VII,[36] protein C,[10,37] protein S,[15] and the protein C inhibitor[16] were isolated as previously reported. All proteins were homogenous and showed the characteristics of published preparations as judged by sodium dodecyl sulfate (SDS)–polyacrylamide gel electrophoresis with and without a reducing agent.[38]

Antisera and neutralization. All antisera used in this study were generated in rabbits as previously reported.[36] For neutralization studies, the IgG fraction of serum was isolated as previously described.[36] Supernatants from four- and five-day serum-free cultures were concentrated 20-fold by ultrafiltration. A constant volume of supernatant was mixed with equal volumes of varying concentrations of specific antibody, and after incubation for 15 minutes at 37 °C, the samples were assayed for biologic activity. Activity values were expressed as percentages of pooled normal human plasma (NHP). Immunopurification of antibodies was accomplished by affinity chromatography on columns constructed of protein C, protein S, or factor VII coupled to cyanogen bromide–activated Sepharose 4B (Pharmacia Fine Chemicals, Piscataway, NJ).

Immunoassays. Double antibody competitive inhibition equilibrium radioimmunoassays were constructed for factor VII,[36] protein S,[35] and protein C. Proteins were radioiodinated by the iodogen method to specific activities of 1.5 to 7.4 μCi/μg.[39] Briefly, to 250 μL of labeled protein (0.5 nmol/L) was added 250 μL of competitor (protein, plasma, or culture supernatant) and 250 μL of antibody diluted to give between 25% to 50% binding of the iodinated ligand. Following incubation at 4 °C for 16 to 20 hours, 250 μL of goat antirabbit IgG was added and incubated at 4 °C for an additional six hours. The immunoprecipitates were collected by centrifugation at 2,000 g for 15 minutes, and 500 μL of the supernatant was counted for radioactivity in an Iso-Data 20/20 series gamma counter (Iso-Data Inc, Palatine, Ill). The buffer used for the assay contained 42 mmol/L borate, pH 8.3, 25 mmol/L NaCl, 10 mmol/L benzamidine, 1 mmol/L phenylmethylsulfonylfluoride (PMSF), 10 U/mL Trasylol, 1.25% heat-inactivated normal rabbit serum, and 0.02% sodium azide.

Protein C and protein C inhibitor concentrations were determined using a radiolabeled Laurell electroimmunoassay, and protein S was assayed by a Coomassie-stained Laurell rocket assay.[40,41] The IgG fraction of antiserum was isolated and radiolabeled with Na ^{125}I (Amersham Corp, Arlington Heights, Ill) by the chloramine T method.[40] Antiserum to protein C or its inhibitor was supplemented with labeled antibody (1 × 10^6 cpm) and added to 0.9% agarose in Tris-barbital buffer, pH 8.4. Samples (8 μL) were electrophoresed overnight at a constant current (10 mA/per slide) at ambient temperature. Slides were washed extensively, dried, and autoradiographed. The same procedure was used for protein S, except labeled IgG was not included and the slides were stained with Coomassie blue after extensive washing. The log concentration of the protein being assayed was linearly correlated to the height of the rocket. The unknown samples were expressed as a percentage of a NHP pool.

Activity assays. Factor VII activity was determined in a one-stage coagulation assay.[36] To 50 μL of plasma immunochemically depleted of factor VII was added 50 μL of plasma diluted in 20 mmol/L tris(hydroxymethyl) aminomethane (Tris) (pH 7.4) containing 140 mmol/L NaCl (TBS) and 1 mg/mL bovine serum albumin (BSA) or 20-fold concentrated Hep G2 supernatant. After incubation for one minute at 37 °C, 100 μL of prewarmed rabbit brain thromboplastin containing 12.5 mmol/L $CaCl_2$ (Simplastin, General Diagnostics, Morris Plains, NJ) was added and the time for clot formation determined. Activities were quantitated and presented as a percentage of pooled NHP.

Human protein C was assayed for its chromogenic activity by the method of Comp et al.[42] Thrombin-thrombomodulin was used to activate protein C, and anti–protein C IgG-Sepharose was used to isolate the activated molecules. The activity of activated protein C was determined using the synthetic substrate S2238 (Helena Laboratories, Beaumont, Tex) as described previously.[40,42] The concentration of protein C in the sample correlated with the linear change in absorbence. The protein C inhibitor activity was assayed as described by Marlar et al.[40] An inverse relationship between the absorbence generated by a fixed amount of activated protein C and the concentration of protein C inhibitor was found and used for construction of a standard curve. Protein S activity in the conditioned medium was assayed by the method of Comp et al.[43] There was a linear relationship between the clotting time and the concentration of protein S. The levels of each factor were expressed as a percentage of a NHP pool.

Immunoprecipitation. Cultures of Hep G2 cells were grown for ten days, washed, and incubated with 4 mL of methionine-free minimum essential medium containing 1 mmol/L benzamidine, 10 μg/mL vitamin K, 1 U/mL heparin (Sigma Chemical Co.) and 150 μCi/mL of ^{35}S-methionine (Amersham Corp). After five to six hours, the supernatants were collected and clarified by centrifugation at 100,000 g for 45 minutes at 4 °C. The supernatants were supplemented with BSA (5 mg/mL) and cleared using *Staphylococcus aureus* previously washed in immunoprecipitation buffer (IPB; 12.5 mmol/L borate, pH 8.3, containing 7.5 mmol/L NaCl, 0.05% Tween 20, 0.5% Triton X-100, 1% Nonidet P-40, 10 mmol/L benzamidine, 1 mmol/L PMSF, 5 U/mL Trasylol, and 0.02% NaN_3).[30] Aliquots were incubated with immunopurified antibodies or the IgG fraction (5 to 10 μg) of normal serum or antisera to factor VII, protein C, protein S, or protein C inhibitor in the presence of 25% (vol/vol) IPB. To confirm a precipitated band as a specific protein, we included 50 μg of the purified protein to compete with the labeled molecule for the specific antibody. After incubation overnight at 4 °C, the immune complexes were collected by the addition of *S. aureus*, incubated for 30 minutes at room temperature and centrifuged in a microfuge for three minutes. The pellets were washed as described previously,[30] and the SDS-soluble material was electrophoresed on SDS–9%-polyacrylamide slab gels[44] containing ^{14}C-protein standards (New England Nuclear, Boston) in the absence and presence of 1% 2-mercaptoethanol. Slab gels were fixed in 10% acetic acid, 25% methanol for one hour, washed extensively with water, incubated with 1 mol/L sodium salicylate for 30 minutes, dried, and subjected to autoradiography.

RESULTS

Cell extracts and supernatants from eight-day cultures were analyzed for the presence of factor VII, protein C, and protein S using sensitive and specific double-antibody–competitive equilibrium radioimmunoassays. The supernatants contained an average of 16.3, 74.0, and 828 ng/mL of factor VII, protein C, and protein S, respectively. Cell extracts were prepared by incubating 7 × 10^8 cells in 1 mL of 1% Triton X-100 containing 10 mmol/L EDTA for 30 minutes at 37 °C and diluting to 2 × 10^8/mL with radioimmunoassay buffer. Factor VII, protein C, and protein S were measured at 8.5, 54.5, and 48.1 ng/mL, respectively. Hence, all three proteins were detected as secreted products and intracellular proteins, provided a sufficient number of cells were used.

To determine if our radioimmunoassay could accurately quantitate the proteins present in the supernatants and cell extracts of Hep G2 cells, we compared the ability of purified proteins, NHP, and a ten-day Hep G2 supernatant to inhibit the binding of iodinated molecules to their respective antibodies. Figure 1 depicts a radioimmunoassay specific for protein C and shows that the protein C in plasma secreted by the cells was immunochemically identical to the purified molecule, as evidenced by the parallel lines of inhibition. Both the plasma and the supernatant did not completely inhibit the reaction, because of the relatively low concentrations of protein C in these preparations. FCS did not compete, indicating that bovine and human protein C are immunochemically distinct. Analogous results were obtained with the radioimmunoassays for factor VII and protein S. Only protein S showed some immunologic cross-reactivity between the bovine and human molecules as reported by others[14,15] and was corrected for in the quantitation. Thus, our assays could accurately measure these three proteins secreted from the cells.

To determine the secretion rates of the vitamin K–dependent proteins from the Hep G2 cells, three T-75 cultures were each seeded with one million cells to give maximal rates of secretion[30] and incubated with 10 mL of culture medium containing serum. On even numbered days, 2 mL of culture medium was removed from each flask and replaced with an equivalent volume of fresh medium. The samples were then quantitated for factor VII, protein C, and protein S by radioimmunoassay, and these values were corrected for the dilution by added medium. Figure 2 shows the increase in each of the proteins with time of culture. However, the absolute amounts of each protein differed with factor VII the least and protein S the greatest. The maximum rates of protein accumulation determined between day 6 and 10 was 5, 25, and 170 ng/mL/d for factor VII, protein C, and protein S, respectively.

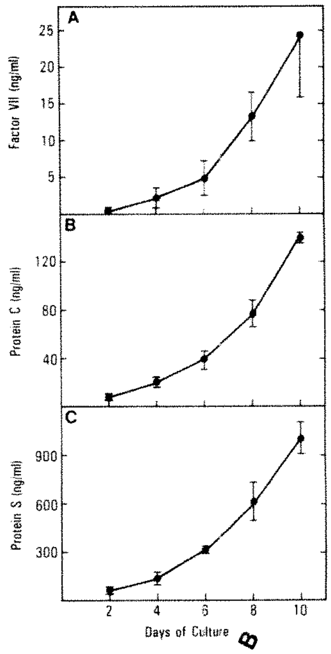

Fig 2. Time course of the accumulation of factor VII (top), protein C (center), and protein S (bottom) in Hep G2 supernatants. Three T-75 flasks were each seeded with 1 × 10^6 Hep G2 cells in the presence of 10 mL of MEM containing 10% FCS. On the days indicated, 2 mL of medium were removed and replaced with fresh medium. Antigen was measured using specific radioimmunoassays. The values were corrected for dilution and are plotted as the mean ± SD (error bars).

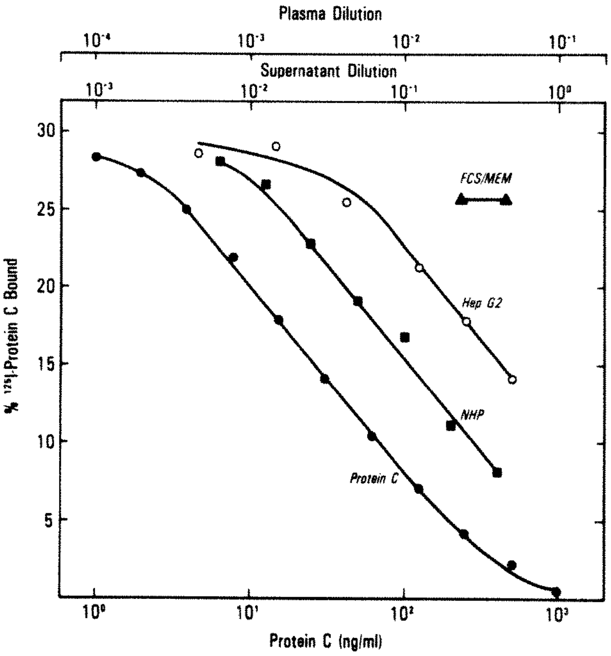

Fig 1. Protein C equilibrium competitive inhibition radioimmunoassay. The binding of ^{125}I-protein C (0.5 nmol/L) to rabbit antiserum (diluted to give 30% binding of the ligand) was inhibited by dilutions of purified protein C (●), NHP (■), ten-day Hep G2 culture supernatant (○) or MEM containing 10% heat-inactivated FCS (▲).

The biologic activity of the secreted proteins was analyzed using specific coagulation assays and compared to the quantity of secreted protein. Activity and antigen values were normalized to NHP for comparison (Table 1). Hep G2 cells were cultured in medium containing serum for 7 days, washed, and cultured an additional four to five days in serum-free medium supplemented with 10 μg/mL vitamin K. The supernatants were collected, clarified by centrifugation, and concentrated 20-fold by ultrafiltration. The activities measured for factor VII, protein C, protein S, and the protein C inhibitor paralleled their respective antigen levels, indicating that the secreted molecules were fully functional with specific activities (activity/antigen) of about 0.96 to 1.23. Further, the activities of each of the four proteins could be specifically neutralized, if the concentrated supernatants were pretreated with their respective antibodies before assay (Table 1). Normal IgG did not significantly affect the function of the four molecules. Thus, these four secreted proteins were biologically active, and their activity could be inhibited by specific antibodies.

Previously, we showed that vitamin K and warfarin modulated the amount of prothrombin secreted by Hep G2 cells.[30] The effect of these agents on the quantity and activity of secreted protein C, protein S, and the protein C inhibitor were studied (Table 2). Seven-day-old cultures were washed and incubated under serum-free conditions in the absence

Table 1. Neutralization of Functional Activities of Factor VII, Protein C, Protein S, and the Protein C Inhibitor Secreted From Hep G2

Protein	Percentage of Antigen*	Treatment†	Percentage of Activity*
Factor VII	4.7	buffer	5.8
		normal IgG	5.3
		anti–factor VII	<0.4
Protein C	50	buffer	52
		normal IgG	53
		anti–protein C	<3

		normal IgG	72
		anti–protein S	<3
Protein C inhibitor	100	buffer	102
		normal IgG	106
		anti–PCI	<3

*Activity and antigen values are presented as percentages of pooled NHP.

†Supernatants were incubated with buffer, normal, or immune IgG (40 nmol/L) for 15 minutes at 37 °C and then assayed for activity.

Serum-free culture medium from Hep G2 cells was concentrated 20-fold by ultrafiltration.

and presence of 10 μg/mL vitamin K or 1 μg/mL warfarin for an additional four days. The concentration of these proteins remained constant (protein C) or increased slightly (protein S) in the presence of vitamin K. When the cells were cultured in the presence of warfarin, a three- to fivefold reduction in the total accumulated protein C and protein S was observed by electroimmunoassay (Table 2) or radioimmunoassay (data not shown). Accumulation of the protein C inhibitor (Table 2) and the total secreted protein (data not shown) were unaffected by either treatment. Functional activity of protein C, protein S, and factor VII was decreased by 50% to 90% in the presence of warfarin, whereas the protein C inhibitor activity was not affected. Also, protein C and protein S activities were disproportionately lower than their respective antigen values. For protein C, a tenfold reduction of activity was observed compared to only a threefold reduction in antigen. The protein S activity decreased fourfold, whereas the antigen only decreased 2.5-fold in the presence of the vitamin K antagonist.

Table 2. The Effect of Warfarin and Vitamin K on the Secretion and Activity of Protein C, Protein S, the Protein C Inhibitor, and Factor VII

	Protein C		Protein S		PC Inhibitor		Factor VII
	Act*	Ag*	Act	Ag	Act	Ag	Act
Control	45	42	60	67	85	86	25
Vitamin K	45	47	77	75	86	80	23
Warfarin	3	16	15	28	88	80	10

*Antigen (Ag) quantitation was by electroimmunoassay and activity (Act) was measured in coagulation or amidolytic assays as described in Materials and Methods. Values are presented as the percentage of normal human plasma for each individual protein.

T-75 flasks were cultured for seven days in medium containing 10% FCS. After washing, the cells were incubated for four days in the presence of MEM (control), medium containing 10 μg/mL vitamin K or medium containing 1 μg/ml warfarin. Supernatants were concentrated 20-fold by ultrafiltration before analysis.

To demonstrate the synthesis of these proteins by the Hep G2 cells, cultures of 10-day-old cells were washed and incubated with methionine-free MEM containing 150 μCi/mL of ^{35}S-methionine for six hours at 37 °C. After centrifugation, the supernatants were immunoprecipitated and electrophoresed on SDS-polyacrylamide slab gels in the absence and presence of a reducing reagent. In selected experiments, excess unlabeled protein was added to the supernatant as a competitor before immunoprecipitation. Figure 3 depicts autoradiographs of the slab gels under reduced conditions. Factor VII and protein S were precipitated as single-chain species with apparent mol wts of 52,100 ± 1,600 and 77,300 ± 1,000, respectively. The antibody to the protein C inhibitor was known to recognize at least one other plasma protein. Therefore, to identify which of the components represented the inhibitor, we included 50 μg of highly purified protein C inhibitor in the immunoprecipitation reaction and looked for the mol wt band diminished in the presence of the added protein. Of the two major bands observed in the gel, only one was displaced by added inhibitor and corresponded to an apparent mol wt of 58,000 ± 800. Two minor bands of about 98,000 and 77,000 also appeared to decrease with addition of excess protein C inhibitor. Protein C migrated as a single, diffuse component with a mol wt of approximately 65,000 ± 3,000, indicating that protein C was secreted as a single-chain molecule. The addition of

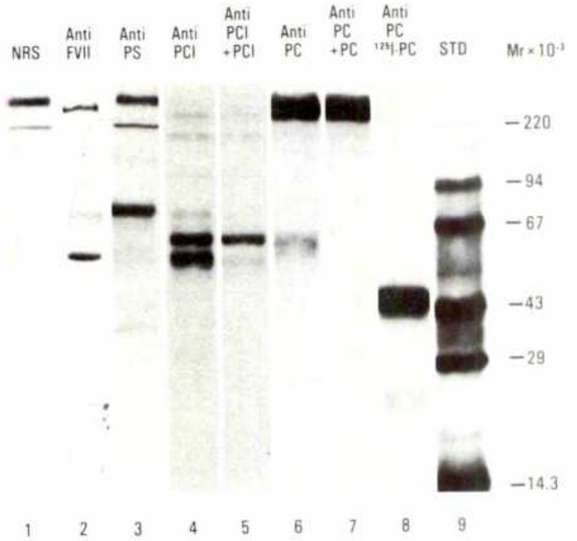

Fig 3. Autoradiogram of the immunoprecipitates from ^{35}S-methionine-labeled proteins secreted from Hep G2 (lanes 1 to 7) and ^{125}I–protein C (lane 8) following incubation with normal rabbit IgG (lane 1), anti-factor VII (lane 2), anti–protein S (lane 3), anti–protein C inhibitor (lanes 4 and 5) or anti–protein C (lanes 6 to 8), and precipitation with *S. aureus* and SDS polyacrylamide gel electrophoresis in the presence of 2-mercaptoethanol. Purified protein C inhibitor (50 μg; lane 5) or protein C (50 μg, lane 7) was added to the supernatants before immunoprecipitation. Standards used for quantitation (lane 9) contain myosin (220,000), phosphorylase b (94,000), BSA (67,000), ovalbumin (43,000), carbonic anhydrase (29,000), and lysozyme (14,300).

excess purified protein C before immunoprecipitation prevented recovery of this band. We did not observe mol wt bands in these precipitates that would correspond to the heavy and/or light chain of protein C. For comparison, iodinated purified protein C was added to the medium and immunoprecipitated under the same conditions as the Hep G2 supernatants. The characteristic two-chain form of protein C was seen with apparent mol wts of 45,000 ± 700 and 25,500 ± 2,000 for the heavy and light chains, respectively. Although the heavy chain is clearly evident, the light chain was much fainter, indicating a disproportionate iodination of the polypeptides. However, prolonged exposure time facilitated the detection of the light chain.

DISCUSSION

The Hep G2 cell has been shown to synthesize and secrete many of the proteins thought to be derived from the liver.[26-30,45,46] The molecules of the coagulation and fibrinolytic systems demonstrated to be the product of this cell reflect their plasma counterparts structurally, immunochemically, and functionally.[26-30] In this report we have extended these studies to include molecules that can initiate (factor VII) and regulate (protein C, protein S, and protein C inhibitor) the coagulation process. In each case, these molecules were biologically active, neutralized by specific antibodies, modulated by known pharmacologic agents, and were structurally and immunochemically similar to the molecules isolated from plasma. Thus, this study provides the first direct evidence that the soluble components of the protein C pathway are produced by the liver and confirms the synthesis of factor VII by hepatocytes.

The finding that protein C is synthesized and secreted as a single-chain molecule is consistent with recently reported data from recombinant DNA (cDNA) cloning indicating that protein C is transcribed as a single contiguous messenger RNA (mRNA),[47,48] and from immunoblotting experiments suggesting that 10% of plasma protein C is present in a single-chain form.[49] Recently, single-chain protein C has been isolated from plasma and has the same activation and enzymatic properties as the two-chain form.[50] Similar findings have been reported for factor X, the only other two-chain vitamin K–dependent protein.[25,30,51-53] Thus, all of the molecules in this protein family appear to be the products of individual genes. Because we immunoprecipitate only secreted material, protein C and factor X must undergo a postsecretion processing event leading to the generation of their respective two-chain plasma forms. The nature of this modification remains to be elucidated. It is possible that a minor population of protein C is processed during secretion. However, prolonged exposure of our gels did not reveal the presence of any other mol wt bands that could be specifically competed by addition of purified protein C before immunoprecipitation. Thus, within the limitations of this analysis, only single-chain protein C is secreted from the Hep G2 cells.

Synthesis of factor VII by the liver has been demonstrated using rodent organ perfusates, preparation of liver microsomes, and the use of established rat cell lines.[21,22,31-33] All of these investigations have been limited to the use of activity measurements in coagulation assays to make their conclusions. Because human factor VII has been isolated in sufficient quantities and monospecific antibodies made to it,[36] the appropriate reagents were in hand to unequivocally establish the human hepatocyte as a site of origin of this molecule. Characteristics of the secreted protein were very similar to those of the isolated molecule with a mol wt of about 50,000[5,6,36] and a similar immunochemical profile. Extrapolation to normal tissue from the findings in a tumor cell must always be guarded; however, very similar correlations between proteins isolated from plasma and characterized from this cell line make our conclusions tenable.

Protein S and the protein C inhibitor shared the same properties as their isolated plasma counterparts. Protein S had an apparent mol wt of 75,000 to 77,000 under reduced conditions, indicating that it was synthesized and secreted as the mol wt form originally reported[14] but was smaller than the more recently published measurements of 84,000 daltons by Dahlback.[15] We saw no evidence of proteolysis since mol wt estimates in reduced and nonreduced gels were similar and no degradation was seen if iodinated protein S was added to cell lysates. Immunochemically and functionally, the secreted molecule was identical to the isolated plasma form. Secretion of protein S from these cells appears very efficient when compared to the other vitamin K–dependent proteins. The quantity of intracellular protein S is less than that measured for prothrombin, and the rate of secretion is about 50% greater. This may be attributed to different secretion mechanisms or to differences in culture conditions (ie, serum lots) and age of the cells (about 30 more passages in this study relative to the prothrombin analysis). Both protein C and factor VII have high secretion rates relative to factor X. This may also reflect a normal process since both protein C and factor VII have shorter half-lives and, therefore, would require higher synthetic rates to maintain a steady state. The protein C inhibitor was also very similar to its recently reported plasma counterpart functionally, immunochemically, and structurally.[16,17] Thus, all the soluble components of the protein C pathway are produced by the hepatocyte.

One of the principal characteristics of the family of vitamin K–dependent proteins is the effect of warfarin-like drugs on the synthesis of these molecules. Previously, we demonstrated that prothrombin and factor X, but not antithrombin III, were accumulated in the culture medium at a lower rate than untreated cells.[30] Protein C and protein S were shown to be similarly affected, with a reduction in the amount of each protein by about three- to fourfold. Protein C inhibitor, a protein thought not to be modulated by these drugs, was unaffected in the amount of secreted antigen and activity. The functions of protein C, protein S, and factor VII were significantly decreased in the presence of warfarin, and this reduction was greater than that observed for accumulated antigen. This indicates a decrease in the specific activity of the secreted molecules and is consistent with the findings obtained from patients undergoing warfarin therapy.[34-36] Vitamin K did not significantly increase production of these molecules as observed with prothrombin.[30] It is possible that prothrombin synthesis is more sensitive to vitamin K or that the concentration of vitamin K in our lot of FCS was optimal to produce and maintain a maximal rate of synthesis over the serum-free culture period. This latter suggestion is supported by the production of fully active proteins by cells not supplemented with exogenous vitamin K. Thus, our results suggest that the decrease in the vitamin K–dependent proteins (measured by antigen) present in the plasma of individuals undergoing warfarin therapy can be attributed to at least a decrease in the synthetic rate of these molecules. Increases in the catabolic rates may also occur and need to be investigated.

The human hepatoma cell line, Hep G2, has been of benefit in our determining the origin of a number of plasma proteins. This cell line has been shown to synthesize and secrete most of the vitamin K–dependent proteins. Factor IX is not transcribed (P. Tolstoshev, personal communication, Transgene, Strasbourg, France, January 1985) or translated by this cell,[30] and protein Z is present in culture supernatants at very low concentrations (D. Fair, unpublished observations, June, 1984). In addition, this cell has the capacity to synthesize and secrete most of the proteins of the coagulation, fibrinolytic, and protein C systems including their inhibitors. Because the cell line responds normally to known pharmacologic modulators, it provides an excellent model to investigate the molecular events underlying these measured responses.

ACKNOWLEDGMENT

We thank David Revak, Kathy McCarthy, and Marsha McDonald for excellent technical assistance and Ellen Schmeding and Joy Lozano for preparation of the manuscript.

NOTE ADDED IN PROOF

After submission of our manuscript Morito et al (Biochim Biophys Acta 844:209, 1985) published the synthesis of the protein C inhibitor by Hep G2 cells. However, these investigators were unable to detect protein C in cell supernatants in contrast to our findings.

Purification of Human Erythropoietin to Homogeneity by a Rapid Five-Step Procedure

By Gerald Krystal, H. Robert C. Pankratz, Neal M. Farber, and John E. Smart

Human urinary erythropoietin (Ep) has been purified using a simple five-step procedure to yield preparations with potencies of 80,000 U/mg in 25% yield. The five steps involve: (1) affinity chromatography on CM Affi-Gel Blue, (2) chromatofocusing, (3) wheat germ lectin (or hydroxylapatite) chromatography, (4) reverse-phase high-performance liquid chromatography (HPLC) using a phenyl column, and (5) preparative sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Ep activity was determined at each stage using a highly sensitive and specific in vitro assay that measures [^{3}H]-thymidine incorporation into erythroid cells from spleens of phenylhydrazine-treated mice. The step 5 material was also tested with the in vivo polycythemic mouse assay procedure and was found to have a similar potency to that obtained in the [^{3}H]-thymidine in vitro assay. SDS-PAGE analysis of the step 5 material revealed a single 38.5-kd band that co-migrated with Ep bioactivity. Homogeneity was confirmed by amino acid sequence analysis. Starting with urine containing ~13 U/mg of protein, the cumulative degrees of purification achieved with each step were: step 1, 25-fold; step 2, 75-fold; step 3, 300-fold; step 4, 1,500-fold; and step 5, 5,000-fold. Corresponding overall recoveries after each step were: >100%, 70%, 45%, 30%, and 25%. These recoveries could be obtained when as little as 5,000 U of starting urinary Ep were processed because of the introduction of Tween 20 and SDS into buffers used at various stages of the purification procedure. In addition, a rapid method for determining Ep purity which involves reverse-phase HPLC of trypsinized ^{125}I-labeled Ep is presented. This allows the establishment of purity with far less material than is required for amino acid sequencing.

© 1986 by Grune & Stratton, Inc.

IT IS NOW well established that erythropoietin (Ep) plays a major role in regulating the terminal phases of erythropoiesis.[1,2] However, very little is known about the mechanism of action of this hormone, owing, in large part, to difficulties historically encountered in acquiring sufficient quantities of highly purified preparations. In 1977, Miyake et al were the first to publish a procedure for purifying human Ep to homogeneity using classical biochemical techniques.[3] This method used eight lengthy steps and gave only reasonable yields (15%) when very large amounts of starting material were used, ie, 2,500 L of starting urine containing 7 million U of Ep. This amount of starting material is not available to most laboratories involved in Ep research. Recently, Yanagawa et al reported a simple two-step procedure for purifying Ep to homogeneity that involved an immunoadsorbent column of monoclonal antibodies to sodium dodecyl sulfate (SDS)-denatured Ep.[4] Although this procedure represents a major advance over the original approach, it is contingent upon access to a suitable monoclonal antibody. Such antibodies are not yet widely available, and alternative methods thus continue to be of interest.

In this report, we describe a simple five-step protocol for purifying Ep to homogeneity that yields a 25% final recovery even when as little as 5,000 U of starting urinary Ep are used. We believe this is possible because of the introduction of ionic (ie, SDS) and nonionic (ie, Tween 20) detergents into the buffers used at various stages of the purification procedure. This appears to reduce the adsorption of Ep to glass and plastic surfaces markedly.

We also describe a rapid procedure for determining Ep purity that involves reverse-phase high-performance liquid chromatography (HPLC) of trypsinized ^{125}I-labeled Ep. Using this procedure, pure Ep yields two clearly defined peaks of radioactivity. This therefore allows the establishment of Ep homogeneity without the need for amino acid sequence analysis.

MATERIALS AND METHODS

Materials

Polybuffer exchanger 94 (PBE94), polybuffer 74 (PB74) and wheat germ Lectin-Sepharose 6MB (~5 mg lectin/mL sedimented gel) were purchased from Pharmacia Fine Chemicals, Montreal. CM Affi-Gel Blue, hydroxylapatite (Bio-Gel HTP), and the electrophoresis purity reagents, acrylamide, bis acrylamide, TEMED, and ammonium persulfate were obtained from Bio-Rad, Richmond, Calif. The μBondapak phenyl HPLC column (0.39 × 30 cm) was acquired from Waters Associates, Milford, Mass. The Spectra-Physics 8000 HPL chromatograph was purchased from Technical Marketing Associates, Vancouver, Canada, and the UA-5 absorbance/fluorescence monitor used for HPLC was obtained from Isco, Lincoln, Neb. Insoluble neuraminidase (*N*-2382), polyethylene glycol (PEG) 4000 and 6000, Triton X-100 (TX100), sodium deoxycholate (DOC) (D-6750), Tween 20 (monolaurate polyoxyethylenesorbitan), human transferrin (T-2252), bovine serum albumin (BSA) (A-7638), and silver nitrate were obtained from Sigma, St Louis. Nonidet P40 (NP40) was purchased from Particle Data Laboratories Ltd, Elmhurst, Ill; SDS, specially pure, was purchased from BDH Chemicals, Toronto. For HPLC, *n*-propanol (spectrophotometric grade) was purchased from Aldrich Chemical Co, Milwaukee.

Urine Collection and CM Affi-Gel Blue Chromatography

Urine was collected from aplastic anemic patients whose urinary Ep titers had been previously established as >0.5 U/mL. The urine was frozen immediately after excretion and was stored at −15 °C. Subsequent preparation for CM Affi-Gel Blue chromatography and the details of this first step in the purification procedure have been described previously.[5]

Assay for Ep

A microassay procedure for Ep, based on the incorporation of $[^3H]$-thymidine into spleen cells from phenylhydrazine-treated mice,[6] was used throughout this study. Ep content of fractions obtained at different stages of purity were determined by comparison with either the World Health Organization (WHO) standard preparation No. 2[7] or CM Affi-Gel Blue purified human urinary Ep (100 to 350 U/mg)[5] calibrated against the WHO standard.

The Ep activity present in the purest preparation (step 5 Ep) was also determined in vivo using the polycythemic mouse assay (five mice per sample).[8]

Protein Determination

Protein concentrations for all but the last step in the purification procedure were measured using the Coomassie Brilliant Blue G-250 dye-binding technique of Bradford with BSA as the protein standard.[9] For the final electrophoretically pure Ep preparation, protein content was determined by silver-staining analytical SDS polyacrylamide gels using a modified Ohsawa and Ebata procedure,[10] scanning the gels using a Hoefer Scientific GS300 Transmittance/Reflectance scanning densitometer (San Francisco), and comparing the Ep area to known protein standards.

Stabilization Studies

Under sterile conditions, step 2 Ep (refer to Table 1 for definition of steps) at 2,750 U/mg; 1,100 U/mL was diluted to 500 mU/mL with PBS [10 mmol/L of phosphate-buffered saline (PBS)]. Immediately following this dilution, 100-μL aliquots were dispensed into 12 × 75 mm tubes (Falcon, Oxnard, Calif) containing either 10 μL of 10% bovine serum albumin (BSA); 1% SDS, 0.2% Tween 20, 1% BSA, 10% polyethylene glycol (PEG) 6000, 0.1% NP40, 0.1% TX100, 0.1% DOC, or PBS. Concentrated step 2 Ep (1,100 U/mL) was also diluted to 500 mU/mL with 0.15 mol/L of NaCl, and 100 μL was added to a Falcon tube containing 10 μL of 100 mmol/L of $CaCl_2$. Control tubes were also prepared as above but without Ep. Immediately after the dispensing, the two tubes (with and without Ep) containing 10 μL of 10% BSA were frozen, and the remaining tubes were incubated for 12 hours at 23 °C. For the in vitro assay, aliquots were either tested at a final concentration of 20% (ie, 20 μL/100 μL total vol), or were diluted tenfold, with 0.1% BSA in α minimal essential medium (MEM) without nucleosides and were tested at a final concentration of 2%.

Analytical SDS-PAGE

To assess the electrophoretic purity at each stage of the purification procedure, samples were made at 2% with SDS, 5% with 2-mercaptoethanol, and 10% with glycerol, and were heated to 100 °C for two minutes. They were then subjected to standard SDS-PAGE as described by Laemmli[11] using either 8%, 10%, or 12% acrylamide running gels, 0.85-mm thick by 14-cm long. Following electrophoresis, some gel lanes were sliced into 0.5-cm sections, placed in 1.5-mL polypropylene microcentrifuge tubes (VWR Scientific Inc, San Francisco), and rocked overnight at 4 °C with 0.5 mL of 0.02% Tween 20 in PBS. Microfuged supernatants were then assayed for activity using the $[^3H]$-thymidine assay procedure.[6] The rest of the gel lanes were stained using a modified Ohsawa and Ebata silver-staining procedure.[10]

Tryptic Fragment Preparation and Analysis

Approximately 100 ng of step 5 Ep in 50 mmol/L of sodium phosphate (Ph 7.4), 1% SDS was iodinated with 1 mCi $[^{125}I]$-NaI (NEN) using 0.5 mg/mL of chloramine T[12] for three minutes at room temperature. The 25-μL reaction mixture was then treated with 5 μL of 5 mg/mL sodium metabisulfite and 50 μL of 2 mg/mL KI and was passed over a 15 × 0.7 cm Sephadex G-25 (medium) column equilibrated with 0.1% SDS. The peak fractions were pooled, lyophylized, and resuspended in 80 μL of Laemmli loading buffer, boiled for five minutes, and electrophoresed on a 15% SDS-polyacrylamide gel. The region of the gel containing the labeled protein was visualized by one-hour autoradiography of the wet gel. The protein band was excised, and the gel piece was shaken in 50 mL of 40% methanol, 10% acetic acid for two hours with one change, to remove SDS. The gel was then minced, lyophilized, and resuspended in 5 mL of 0.1 mol/L of ammonium bicarbonate. Five microliters of 10 mg/mL TPCK trypsin (Worthington Biochemicals, Millipore Corp, Bedford, Mass) was added, and digestion proceeded for 18 hours at 37 °C. Another 5 μL of trypsin was added for another two hours at 37 °C. The digested fragments were washed through a 0.45-μm millipore HA filter with 0.1 mol/L of ammonium bicarbon-

ate and lyophilized. For the reverse-phase chromatography of tryptic peptides, the peptides were dissolved for ~ten minutes in 100 μL of 90% formic acid at 23 °C and were then diluted with 400 μL of H_2O. The sample was then applied to a 4.6-mm × 25-cm Spherisorb 10 ODS (C_{18}) reverse phase column (Spectra-Physics). The column was run at 40 °C and at a flow rate of 1.4 mL/min. After injection of the sample, the column was washed for five minutes with 4.5% formic acid (PSC Reagents, J.T. Baker, Phillipsburg, NJ) and was then developed with a linear gradient from 0% to 62.5% ethanol (Photrex Reagents, J.T. Baker) in 4.5% formic acid over a period of 95 minutes on a Beckman 345T HPLC system. Fractions of 0.7 mL were collected in 0.5 minute each, yielding a total of 200 fractions; each fraction was counted in a Beckman 5500 gamma counter.

Amino Acid Sequencing

Approximately 10 μg of step 5 Ep was dialyzed against 0.01% SDS, lyophilized, and resuspended in 100 μL of H_2O. The sample was boiled, and 10 μL was removed for amino acid analysis. The remaining aliquot was sequenced on an Applied Biosystems Gas Phase Sequencer model 470A using MeOH/HCl conversion. The PTH amino acids were analyzed on a Hewlett Packard 1084B HPLC with model 1040A diode array detector.[13]

RESULTS

"Stabilization" Studies

During our initial studies into the purification of Ep, we discovered that substantial losses in activity were incurred as homogeneity was approached. This was particularly evident when purifications were carried out with <10,000 U of starting material (human urine). Subsequent experiments suggested that losses were owing, in large part, to sticking of Ep to glass and plastic surfaces, and that this adsorption could be prevented by the addition of 0.1% BSA or 0.1% SDS to our Ep preparations.[5] Evidence is now presented, following a more extensive survey of potentially "stabilizing" compounds, that 0.02% Tween 20 is as effective as BSA or SDS for maintaining bioactivity of partially purified Ep preparations (Table 2). One percent PEG 6000, 0.01% NP40, and 0.01% TX100 were also found to be effective, although they were less effective than either Tween 20, BSA, or SDS. Little or no protective effect was observed with 0.01% DOC or 10 mmol/L of calcium chloride. Moreover, TX100 and NP40 were toxic in the phenylhydrazine mouse spleen cell assay at final concentrations of >0.001%, whereas SDS was not, at 0.002%; Tween 20 was nontoxic even at concentrations which effectively prevented adsorption of Ep to plastic ware (0.02%). Because Tween 20 was a nonionic detergent and was therefore unlikely to cause significant changes to the native physical properties of Ep, it was added routinely to buffers used in the purification procedures subsequent to the CM Affi-Gel Blue step.

Table 2. Effect of Various Compounds on Ep "Stability"

Conditions of Storage	Ep Activity Recovered (%)
1% BSA and frozen	100
PBS	3.6
PBS (− Ep)	0
0.1% SDS	51*

1% PEG 6000	28
0.01% TX100	29*
0.01% NP40	36*
0.01% DOC	4.2
10 mmol/L of $CaCl_2$	0*

Ep, erythropoietin; BSA, bovine serum albumin; PBS, phosphate-buffered saline; SDS, sodium dodecyl sulfate; DOC, sodium deoxycholate.

Incubations were carried out as described in Materials and Methods section; samples were assayed, unless otherwise indicated, at a final concentration of 20% using the standard $[^3H]$-thymidine microassay.[5]

*Assayed at a final concentration of 2% because of toxicity at 20%. Controls, without Ep, demonstrated no toxicity at 2%.

Purification Procedure

Aliquots of frozen urines, collected from patients with potentially high Ep titers, were thawed, dialyzed against α MEM without nucleosides, and tested in the $[^3H]$-thymidine suspension culture assay at a final concentration of 10%. Those urines containing Ep levels >0.5 U/mL were used for purification. This preliminary screening was essential since, in our experience, only about one-third of the aplastic anemic patients with hemoglobins of <6 g/dL showed urinary Ep titers significantly >0.01 U/mL. Selected urines were then decanted through four layers of Curity Hospital towels, made 0.025 mmol/L with phenylmethyl sulfonyl fluoride and 0.025% with phenol, and were pressure-filtered through a Sartorius Separator and a type SM 13400 membrane filter (Canlab, Vancouver, Canada) as described previously.[5]

CM Affi-Gel Blue fractionation. This step has already been described in detail.[5] In brief, filtered urine was applied at 4 °C to a CM Affi-Gel Blue column (40 mL/mL gel) preequilibrated with 0.15 mol/L of NaCl and 10 mmol/L of Na phosphate (pH 7.2). Under the conditions used, Ep bound to the column whereas most of the applied protein did not. Ep was subsequently eluted, using a steep salt gradient from 0.15 mol/L to 1.15 mol/L of NaCl in 10 mmol/L of Na phosphate buffer. A typical elution profile is shown in Fig 1. Ep eluted as a broad peak, suggesting heterogeneity, at ~0.9 mol/L of NaCl. The column was then regenerated at 23 °C with 8 mol/L of urea. This fractionation procedure routinely gave a 25-fold to 50-fold purification of Ep, with an apparent Ep recovery in excess of 100%. Typically, specific activities following this step were in the range of 100 to 350 U/mg.

Chromatofocusing. The Ep-containing fractions from CM Affi-Gel Blue chromatography were pooled, concentrated ~tenfold by ultrafiltration using an Amicon Model 402 apparatus (Amicon Corp) fitted with a PM10 membrane, and dialyzed overnight at 4 °C against buffer A (20 mmol/L of Tris-Cl, 0.1% PEG 4000 [pH 7.0]). This step 1 Ep was then applied to a PBE94 column (6,000 U/mL of gel) preequilibrated with buffer A. Five-milliliter fractions were collected at 4 °C at a flow rate of 10 mL/h. Buffer A was then run through the column until the OD_{280} returned to baseline, and the column pH was slowly reduced to 3.8 with diluted PB74 (13 mL of PB74 plus 187 mL of distilled water) that had been adjusted to pH 3.8 with 1 mol/L of HCl. Five-milliliter fractions were again collected, this time into tubes containing 0.125 mL of 1 mol/L Tris-Cl (pH 7.5) and 0.10 mL of 1% Tween 20. When the eluate reached pH 3.8,

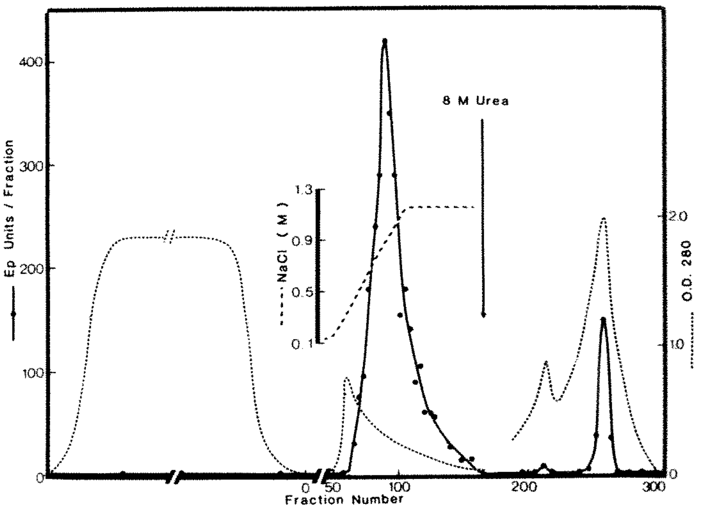

Fig 1. CM Affi-Gel Blue chromatography of filtered human urine. See ref. 5 for complete details.

the column was restored to pH 7.0 with buffer A. To elute most of the Ep activity, 0.3 mol/L of NaCl in buffer A was then applied, and 1.0-mL fractions were collected (into tubes containing 0.02 mL of 1% Tween 20) at 4 °C and at 10 mL/h. Last, 3 mol/L of NaCl in buffer A was put through the column to remove tightly bound proteins and regenerate the gel. A typical profile is shown in Fig 2.

Chromatofocusing was found to be superior to diethylaminoethanol (DEAE) Sephacel chromatography in terms of both column capacity and recovery of Ep activity. Moreover, we found that recoveries were far higher when the pH was returned to 7.0 and when the Ep was eluted with high salt rather than when the pH was either lowered below the isoelectric point of Ep (~3.5) (E. Goldwasser, personal communication) or when eluting was performed with high salt at any pH <4.5. Lowering the pH to 2.9 resulted in the release of only ~50% of the Ep activity; removal of the rest required elution with 0.3 moL/L of NaCl. Although most Ep preparations yielded an elution pattern identical to that shown in Fig 2, approximately one preparation in ten released a substantial amount of total Ep activity (ie, 40% to 50% in some cases) during the initial lowering of the pH to 3.8. This latter elution pattern could be duplicated by treating preparations that gave the standard elution profile with neuraminidase-agarose beads, suggesting that some Ep preparations are less sialated than others, possibly due to patient-to-patient variation in Ep glycosylation or increased losses of sialic acid residues during the purification of some preparations.

Wheat germ Lectin–Sepharose 6MB chromatography. Chromatofocused Ep preparations that displayed the typical elution pattern shown in Fig 2 could be further purified using wheat germ affinity chromatography. The use of wheat germ lectin to purify Ep was first described by Spivak et al,[14] and the conditions used here were modified only slightly from those described by Dukes et al.[15] Specifically, the 0.3 mol/L NaCl pool following chromatofocusing was loaded directly onto a wheat germ Lectin-Sepharose 6MB gel bed (8,000 U/mL of gel) previously equilibrated with 0.02% Tween in PBS. Chromatography was carried out at room temperature and at a flow rate of 2 mL/h. Most of the Ep activity was eluted with 10 mol/L of *N*-acetyl-D-glucosamine in PBS containing 0.02% Tween 20, and the column was then regenerated first with 200 mmol/L of *N*-acetyl-D-glucosamine in the same buffer followed by 20 gel bed vol of 0.02% Tween 20 in PBS. Typically, the bulk of

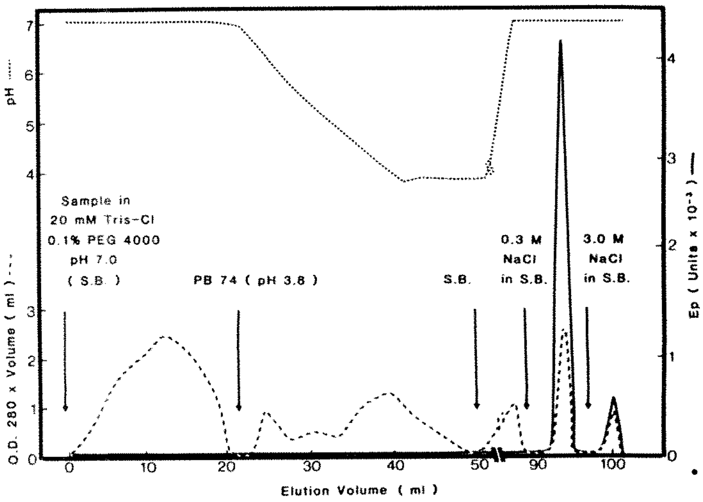

Fig 2. Chromatofocusing of typical step 1 Ep. To monitor the change in pH, every tenth tube did not contain 0.125 mL of 1 mol/L Tris-Cl (pH 2.5). S.B., starting buffer.

the contaminating proteins did not bind to the column, and >90% of the recoverable Ep activity eluted with 10 mmol/L of *N*-acetyl-D-glucosamine (Fig 3). We found that the best purification was achieved if an amount of Ep that closely approached the capacity of the gel was applied, ie, ~8,000 U of chromatofocused Ep per milliliter of gel, using lot No. IF 32137 from Pharmacia Fine Chemicals. However, gel capacity had to be determined through experimentation because it varied markedly from lot to lot. If substantially less than the column capacity of Ep was applied, a significant proportion of the total activity eluted with the 200 mmol/L of *N*-acetyl-D-glucosamine buffer. Using this procedure, we obtained, with most chromatofocused preparations, a fourfold purification with an overall yield of 65%.

Hydroxylapatite chromatography. Approximately one in ten Ep preparations gave an anomalous chromatofocusing profile, consistent with the fact that the Ep in these preparations was less sialated than most of the Ep preparations. The 0.3 mol/L NaCl pools remaining after chromatofocusing of these anomalous preparations were not well suited to wheat germ fractionation, ie, most of the Ep activity did not bind to the lectin. For these preparations, an alternative procedure which involved hydroxylapatite was devised. This chromatographic step was first used by Miyake et al[3] as part of their purification procedure for Ep. However, using their procedure, we achieved extremely low recoveries. This problem could be alleviated somewhat either by applying very high concentrations of protein to the column as Miyake et al[3] did or by adding 0.02% Tween 20 to the chromatographic buffers. This detergent did not appear to interfere with the elution profile. Specific details of the procedure used are given in the legend to Fig 4. Two distinct fractions containing Ep activity were detected, confirming the heterogeneity previously reported with this gel fractionation procedure.[3] When anomalous step 2 Ep was chromatographed on this column, the bulk of the activity eluted with 100 mmol/L of Na/K phosphate (pH 6.8) (Fig 4A), and resulted in a threefold increase in specific activity and a 50% recovery. However, when a typical step 2 Ep preparation was chromatographed, most of the activity eluted between 0 and 10 mmol/L of Na/K phosphate (pH 6.8) (Fig 4B).

Reverse-phase HPLC. Following wheat germ or hydroxylapatite chromatography, the main bulk of Ep activity was concentrated to ~1.5 mL, using an Amicon ultrafiltration unit with a PM 10 membrane, and was loaded onto a 3.9-mm × 30-cm μBondapak phenyl HPLC column equilibrated with 0.1 mol/L of K phosphate (pH 7.0). Samples up to 5 mL, using multiple injections and a 200-μL loop, could be applied with no deleterious effect on subsequent resolution. A biphasic linear 0% to 40% gradient of *n*-propanol in 0.1 mol/L of K phosphate (pH 7.0) was used, and 1-mL fractions were collected into tubes containing a final concentration of either 0.1% SDS or 0.02% Tween 20. Ep eluted as a single peak with ~34% *n*-propanol (Fig 5). Anomalous preparations required slightly more *n*-propanol for elution. This step gave a fivefold increase in purity to ~21,000 U/mg in 70% yield. The active fractions were pooled, dialyzed against 0.01% SDS at 23 °C for six hours, and lyophilized to dryness in preparation for SDS-PAGE.

SDS-PAGE. Ep samples were resuspended in ~2 mL of 62.5 mmol/L of Tris-Cl (pH 6.8), 10% glycerol, and sufficient SDS to give a final concentration of 2%. They were then applied directly to 1.8-mm thick 10% Laemmli gels.[11] The samples were neither heated nor reduced because this diminished subsequent recoveries. Following electrophoresis, 0.2-cm slices above and below the expected Ep region, (assuming an R_f for Ep of ~0.64 compared with the bromphenol blue dye front) were shaken overnight at 4 °C with 0.5 mL of 0.02% Tween 20 in PBS. Centrifuged sample supernatants were assayed for bioactivity as described in the Materials and Methods section, and those fractions containing activity were pooled. Gel slices that contained Ep activity were re-shaken twice with 0.5 mL per slice of 0.02% Tween 20 in PBS, and the three eluates were pooled. Typically, the first extraction released 90% of the recoverable Ep activity, the second released 8%, and the third released 2%. There was total recovery of 85% using this step, and the specific activity was increased ~3.5-fold to 80,000 U/mg.

The five-step purification scheme for Ep from human urine is summarized in Table 1. Overall recovery using this procedure was ~25% as determined by the [^{3}H]-thymidine Ep microassay method. Identical results were obtained using

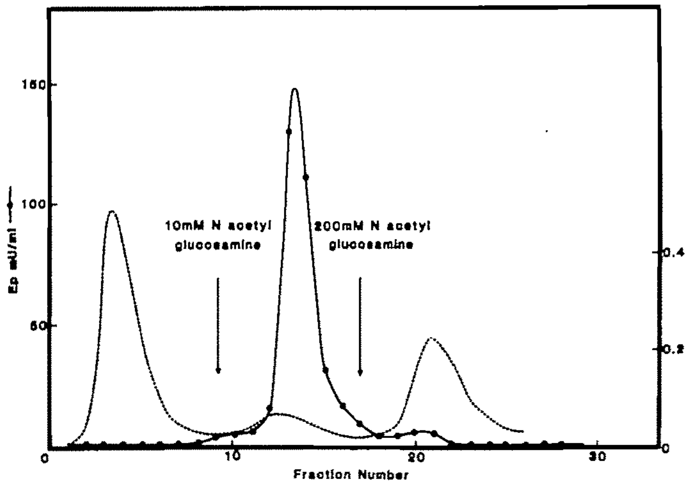

Fig 3. **Wheat germ Lectin–Sepharose 6MB chromatography of typical step 2 Ep.**

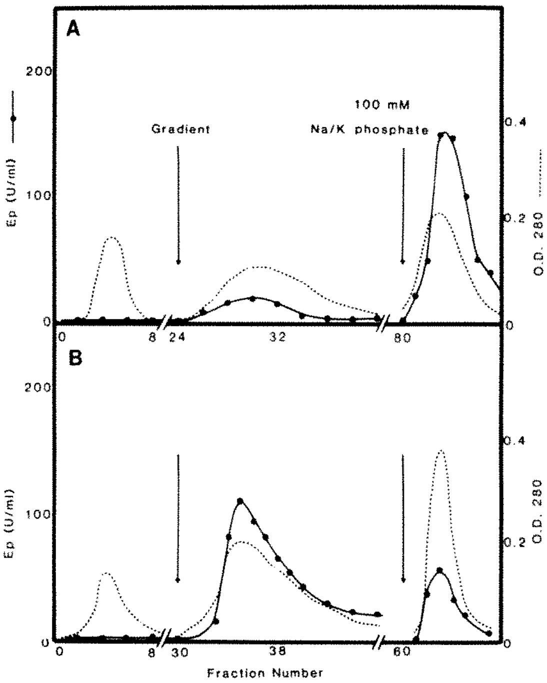

Fig 4. Hydroxylapatite chromatography of (A) anomalous and (B) typical step 2 Ep. One mL of step 2 Ep (1,100 U) was dialyzed against distilled water containing 0.02% Tween 20 and was applied to a 0.5-mL gel bed of hydroxylapatite preequilibrated with distilled water containing 0.02% Tween 20. After administration of the sample, the column was eluted with 0.2% Tween 20 in water, and 1-mL fractions were collected at 4 °C and at 10 mL/h until the OD_{280} returned to baseline. A gradient of 0 to 10 mmol/L of Na/K phosphate was then initiated, using 10 mL of distilled water and 10 mL of 10 mmol/L Na/K phosphate (pH 6.8), both containing 0.02% Tween 20. This was followed by 10 mmol/L of Na/K phosphate until the OD_{280} returned to baseline. Finally, 100 mmol/L of Na/K phosphate (pH 6.8) containing 0.02% Tween 20 was used to elute the remaining activity.

a standard Ep assay based on in vitro ^{59}Fe incorporation.[16] Moreover, the step 5 material was also tested in the in vivo polycythemic mouse assay[8]; the results indicated a potency of 80,000 U/mg, very similar to that obtained with the in vitro assay procedures.

Determination of Purity

Aliquots at each stage of the purification procedure were assessed for purity by analytical SDS-PAGE. For this purpose, samples were reduced with 5% 2-mercaptoethanol and were heated to 100 °C for two minutes. Following electrophoresis, most of the lanes were silver-stained by a modified Ohsawa and Ebata method.[10] The major modification in the silver-staining procedure involved use of 10% glutaraldehyde prior to gel shrinkage with PEG 2000. This was found to make the silver-staining intensity of various test proteins more quantitative, ie, the staining intensity more closely reflected the amount of protein applied to the gels. (G. Krystal and S. Ashwell, unpublished observations) As shown in Fig 6, the final Ep preparation (step 5) appeared as a single broad band on analytical SDS-PAGE; this band coelectrophoresed with Ep bioactivity. Moreover, the average mol wt of this broad band was 38.5 kd, in close agreement with the mol wt assignment reported by Miyake et al.[3] However, the mol wt varied slightly depending on the percentage of acrylamide in the SDS gels. For example, step 5 material appeared to have a mol wt of 39 kd on an 8% gel and 37 kd on a 12% gel. These results are consistent with Ep being a glycosylated protein.[17] One of the anomalous Ep preparations, discussed above, which did not bind to wheat germ and was purified to homogeneity using hydroxylapatite followed by HPLC and preparative SDS-PAGE, appeared to have a mol wt of 32 kd on a 10% acrylamide gel. This is consistent with its being substantially less sialated than most of the Ep preparations which we have purified.

The specific activity of step 5 Ep was estimated by scanning lanes iv and v and comparing their staining intensities with protein standards (Fig 6). This was necessary because the concentration of protein in our eluted step 5 material was too low to determine protein content by more

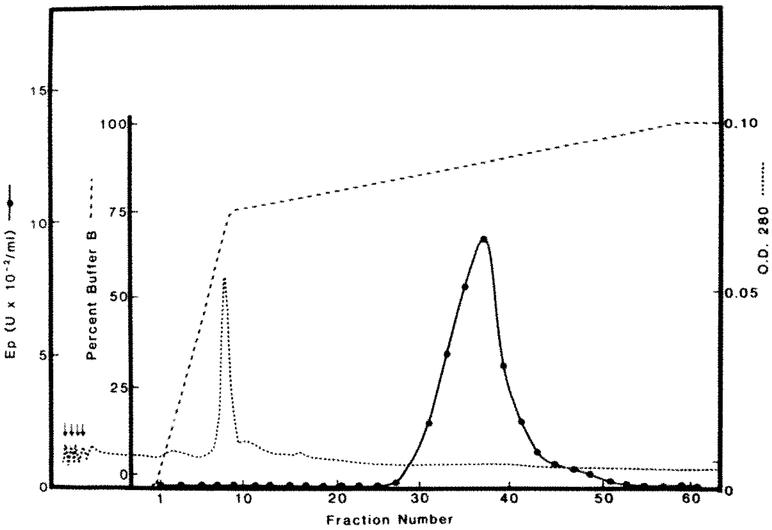

Fig 5. Phenyl high-performance liquid chromatography (HPLC) of step 3 Ep. Approximately 10,120 U (2.4 mg) of step 3 Ep was applied directly, using multiple injections of 200 μL each (arrows indicate the last of these injections), to a 0.39 × 30 cm phenyl HPLC column preequilibrated with 0.1 mol/L of K phosphate (pH 7.0) (buffer A). Chromatography was carried out at 23 °C, at a flow rate of 0.5 mL/min, and 1-mL fractions were collected into tubes containing 10 μL of 10% SDS. For the first five minutes, elution was carried out with buffer A. A biphasic linear gradient was then initiated: at 20 minutes, the percentage of buffer B (40% *n*-propanol in 0.1 mol/L of K phosphate [pH 7.0]) eluting through the column was up to 75%. A shallower gradient was then initiated: at 120 minutes, the column reached 100% buffer B.

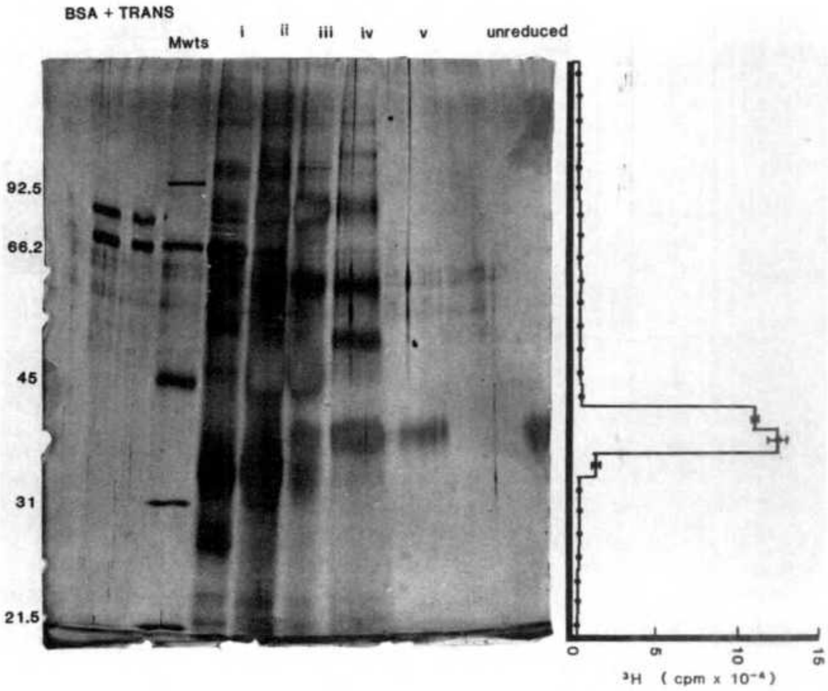

Fig 6. Sodium dodecyl sulfate-polyacrylamide gel (SDS-PAGE) analysis of the Ep fractions from each step in the purification procedure. The gel concentration was 10%. All samples were in 2% SDS, 10% glycerol and 50 mmol/L of Tris-Cl (pH 6.8). Samples applied to lanes 1 through 9 were reduced with 5% 2-mercaptoethanol and were boiled for two minutes. Samples 10 through 12 were neither reduced nor heated. Lanes 1 and 2 contained 100 ng and 50 ng, respectively, of bovine serum albumin and transferrin; lane 3 contained Bio-Rad low mol wt SDS-PAGE standards; lanes 4 through 8 contained Ep of steps 1 through 5, respectively; lane 9 contained reduced and heated SDS sample buffer; lane 10 contained unreduced, unheated SDS sample buffer; lane 11 contained buffer unreduced and unheated step 5 Ep. Lane 12, containing unreduced, unheated step 3 Ep was cut into 0.5-cm slices, shaken overnight in PBS containing 0.02% Tween 20, and bioassayed.

conventional Coomassie,[9] OD_{280},[4] or OD_{278}[3] methods. Scanning of lane iv and measuring of the areas under the peaks demonstrated that 29% of the total silver-staining material was present in the Ep region. Assuming that pure Ep was between 70,000[3] and 80,000[4] U/mg suggested that the HPLC-purified preparation had a sp activity of 20,000 to 23,000 U/mg, consistent with the 21,000 U/mg obtained for this material using Bradford's protein determination method (see Table 1), and lending credence to the scanning of silver-stained gels (using the silver-staining method described above) in order to obtain quantitative data on the protein content of gel bands. Known amounts (50 ng and 100 ng) of BSA and transferrin were electrophoresed on the same gels to help quantitate the amount of protein in lane v (Fig 6); it was determined that, for the same amount of protein, transferrin yielded 75% to 80% of the staining intensity of BSA. Therefore, taking into account band breadth and the fact that 11 U of Ep were applied to lane v, the scanning data suggested that the step 5 Ep preparation was between 69,000 U/mg (based on transferrin) and 89,000 U/mg (based on BSA). This is in close agreement with the previously reported specific activities for pure Ep of 66 U/mg,[18] 70.4 U/mg,[3] and 81.6 U/mg.[4]

Close examination of lanes 1 through 9 in Fig 6 revealed three faint bands between 55 kd and 62 kd. Because only SDS sample buffer with 5% mercaptoethanol was run in lane 9, it was concluded that these proteins were contaminants from the SDS sample buffer and were not present in the Ep preparations themselves. Moreover, these bands were observed when SDS sample buffers containing either mercaptoethanol (lane 9, Fig 6) or dithiothreitol (data not shown) were used but not when SDS sample buffers without reducing agents were used (lanes 10 and 11, Fig 6). These findings are in agreement with previous reports[19,20] which suggest that these contaminants are of human skin origin and that they are far more readily observed in the presence of reducing agents.[20]

Reduced electrophoretically pure Ep migrated marginally slower than did unreduced Ep (lane 12, Fig 6). This is consistent with the presence of an intrachain disulfide bridge in the native molecule, and is in agreement with a recent report by Jacobs et al in which they suggest that at least two of the four cysteines in Ep may be involved in a disulfide bond.[21] It was also noted that unreduced Ep appeared on our SDS gels as a slightly more diffuse band than that of reduced Ep. This may suggest that not all Ep molecules have the same number of disulfide bridges in the native state.

The purity of step 5 Ep was firmly established by amino acid sequencing. The material was subjected to 18 cycles of NH_2-terminal amino acid sequence analysis as described in the Materials and Methods section. Approximately 200 pmols of protein was analyzed by sequential stepwise Edman degradation yielding the following unique polypeptide sequence: ?-?-Pro-Arg-Leu-Ile-?-Asp-Ser-?-Val-Leu-Glu-?-Tyr-Leu-Leu-Glu. The first two amino acids were not determinable because of contamination of the step 5 Ep with glycine and Tween 20 from the electrophoresis step. The sequence obtained is in total agreement with three previously reported Ep sequences.[4,21,22] Consequently, we can explain the lack of scores at positions 10 and 14 by noting that the previously cited Ep sequences predict Arg residues at these positions, which give very low PTH yields and would be below the level of detection in our sample.

Biochemical Characterization of Step 5 Ep

Step 5 Ep was iodinated using [^{125}I]-NaI and chloramine T[12] and was then subjected to trypsin digestion as described in the Materials and Methods section. Reverse-phase HPLC

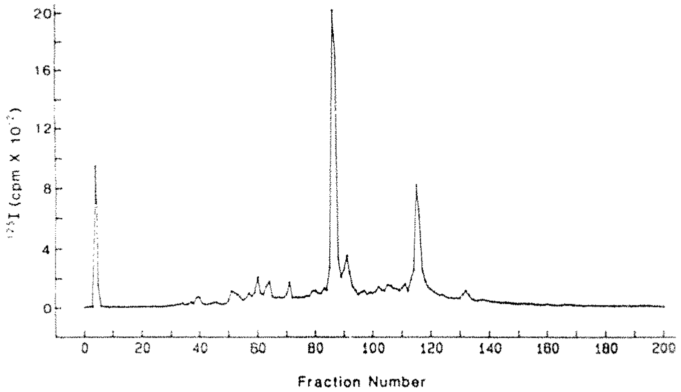

Fig 7. C_{18} high-performance liquid chromatography of trypsinized step 5 Ep.

using a C_{18} column and a linear gradient of ethanol from 0% to 62.5% revealed two well-defined peaks (Fig 7). This profile has been obtained by Smart and Farber (J.E. Smart and N.M. Farber, unpublished observations) with several homogeneous preparations of Ep, including one that they have sequenced extensively (48%) and that shows 100% agreement with the recently published sequence for Ep.[21]

DISCUSSION

In this report, a method for the purification of human urinary Ep to apparent homogeneity is described. The advantages of this method over that previously presented by Miyake et al[3] are: first, fewer steps are used; second, far less starting urine is required to ensure reasonable final recoveries; and third, significantly higher final recoveries (25% *v* 15%) are obtainable. Thus, investigators who have been anxious for homogeneous preparations of Ep but who have been hindered by limited supplies of high Ep titer urine can now obtain ~1,250 U of pure Ep from only 5,000 U of starting urine.

The first two steps in this new procedure, namely CM Affi-Gel Blue chromatography and chromatofocusing, serve not only to purify but to concentrate as well. Thus, these two high-protein-capacity gels are well suited for the first two fractionation steps. The last four steps, ie, chromatofocusing, wheat germ lectin–Sepharose 6MB chromatography, reverse-phase HPLC and SDS-PAGE, all provide information concerning the amount of heterogeneity in the particular Ep preparation being processed. For example, both the anomalous Ep preparations and neuraminidase-treated typical Ep preparations displayed: (1) an increased Ep activity in the unbound flow through and the PB74 fractions following chromatofocusing, (2) less binding to wheat germ lectin beads, (3) a greater proportion of the eluted Ep activity, following hydroxylapatite, in the 100 mmol/L Na/K phosphate pool, and (4) an increased binding affinity to the phenyl-HPLC column, ie, such that elution required higher concentrations of *n*-propanol. This last phenomenon is compatible with these Ep preparations being less sialated, since removal of negative sialic acid residues would be expected to make Ep more hydrophobic and would thus require a more hydrophobic buffer for elution. Finally, some anomalous Ep preparations and neuraminidase-treated typical Ep preparations displayed mol wt as low as 32 kd, significantly lower than the 38.5 kd seen with untreated typical Ep preparations. This dramatic difference in mol wt is not inconsistent with simple desialation of native Ep, since Goldwasser has reported that there are between 16 and 18 sialic acid residues per molecule of native Ep.[23] This ability to assess the degree of sialation during Ep purification is a great asset since it is well established that desialated Ep is without effect in vivo.[24] Thus, for example, researchers who are interested in purifying Ep for therapeutic administration to patients can abort their purification procedure at the chromatofocusing stage if anomalous elution profiles are observed. This feature may also be of more general interest since desialated Ep has been reported to be less stable than the native hormone.[24]

Trypsinized pure ^{125}I-labeled Ep yields two well-defined peaks of radioactivity upon Spherisorb 10 ODS (C_{18}) reverse-phase HPLC. This finding can therefore be used as a fast check of Ep purity since it requires far less time and material (ie, 100-fold less) than does gas-phase amino acid sequencing.

The recently published cDNA nucleotide (and therefore amino acid) sequence for Ep[21] suggests that approximately one-half of the Ep molecule must be contributed by sugar side chains. The availability of both recombinant and human urine-derived Ep should now permit a more detailed examination of the contribution by these sugar moieties. It will also be of value to determine whether recombinant Ep that is glycosylated in non-human cells has a shorter half-life in the human circulatory system than does human urine-derived Ep.

ACKNOWLEDGMENT

It is a pleasure to acknowledge the excellent technical assistance of Chris Macdonald and Barbara Delaplace. The authors are also indebted to Dr Connie Eaves and Dr Keith Humphries for their suggestions regarding the preparation of this manuscript and to Michele Coulombe for typing the manuscript.

Detection of Clonal Excess in Lymphoproliferative Disease by κ/λ Analysis: Correlation With Immunoglobulin Gene DNA Rearrangement

By Nancy Berliner, Kenneth A. Ault, Paula Martin, and David S. Weinberg

Previous studies have suggested that analysis of the distribution of surface immunoglobulin light chain isotypes by flow cytometry provides evidence for monoclonality of B cell tumors and may detect populations of circulating tumor cells in patients with lymphoproliferative disease. We have used simultaneous flow cytometry and DNA restriction enzyme analysis on 58 samples of tissue and blood to determine whether lymphocyte populations detected by "κ/λ" analysis are indeed monoclonal. In >90% of cases, abnormalities detected by flow cytometry correlated with monoclonal rearrangements of immunoglobulin genes as detected by Southern blot analysis. By analyzing tissue and blood from the same patients, we have also demonstrated that monoclonal circulating cells detected by flow cytometry reflect peripheral circulating tumor cells, since DNA from these cells shows the same immunoglobulin rearrangement as DNA from the original tumors in these patients. Although mixing studies suggested that DNA rearrangement studies were more sensitive than was flow cytometry in detecting minor populations of monoclonal lymphocytes, we found only one case in which this affected the diagnostic accuracy of the κ/λ analysis, with one notable exception, that of detection of a monoclonal proliferation of B cells that did not express surface immunoglobulin. The κ/λ test thus offers a powerful diagnostic tool in the evaluation of lymphoproliferative disease.

© 1986 by Grune & Stratton, Inc.

THE EVOLVING understanding of the ontogeny of the B lymphocyte has resulted in the development of immunologic methods that have had a great impact on the diagnosis of lymphoproliferative disease. Most malignant lymphomas are of B cell origin.[1,2] Most B cells, with the exception of very early pre-B cells and mature plasma cells, express immunoglobulin on their surface.[3] Each cell expresses only one light chain type. In normal peripheral blood and lymph nodes, there is usually a mixture of κ-positive and λ-positive cells, with two-thirds of the cells expressing κ and one-third expressing λ. Because lymphoid neoplasms are usually clonal expansions of a single cell, the cells uniformly express the same light chain isotype. Consequently, B cell malignancy can frequently be suspected on the basis of the demonstration of a marked predominance of cells expressing a single light chain type.[4]

The uniform expression of immunoglobulin light chains on monoclonal cell populations has been exploited in the development of a cytofluorometric technique to detect small populations of monoclonal B lymphocytes. This κ/λ technique is based on the direct comparison of surface immunofluorescent staining for κ and λ light chains within a cell population. Evidence of an imbalance in the normal distribution of light chain staining implies the presence of a monoclonal cell population. This technique has been used to show that a large proportion of patients with B cell lymphomas have circulating monoclonal B cells that are morphologically undetectable.[5] κ/λ analysis has also been used to distinguish lymphoid neoplasms from benign reactive processes.[6]

Although it has been assumed that an abnormal light chain fluorescence distribution indicates a monoclonal B cell proliferation, direct proof of this has been lacking. The availability of recombinant DNA techniques has made it possible to confirm that assumption. Immunoglobulin molecules are encoded on discontinuous genes. Early in B cell development, the immunoglobulin loci undergo gene rearrangement to form functional coding units for antibody synthesis. This rearrangement is detectable on analysis of genomic DNA and may provide evidence of monoclonality of B cells at very early stages of B cell development.[7,8] This powerful tool has been used to establish the monoclonality of B cell neoplasms in which the diagnosis is hindered by confusing histology or absence of surface markers and has recently been used to establish that some lymphoid malignancies may in fact consist of more than one clone.[9,10]

In this study, we have used DNA restriction enzyme analysis to assess the validity of the κ/λ test. We have confirmed that the detection of clonal excess by flow cytometry correlates well with the finding of monoclonal immunoglobulin rearrangements by DNA analysis. We have also shown that the detection by κ/λ analysis of small populations of tumor cells in the peripheral blood of patients with lymphoma reflects a population of circulating cells with the same DNA rearrangement as that seen in the primary tumors in those patients. We have identified the circumstances under which DNA restriction enzyme analysis is more informative than flow cytometry in the analysis of small populations of B cells. We conclude that the κ/λ test offers a useful and easily applied method for the diagnosis and analysis of lymphoid malignancy.

MATERIALS AND METHODS

Patient selection. Fifty-eight samples of tissue and peripheral blood from patients at the Brigham and Women's Hospital who had proven or suspected lymphoproliferative diseases were obtained for analysis. Diagnoses are outlined in Table 1. The non-Hodgkin's lymphomas included a broad range of histologic types. Because the

Table 1. Summary of Patients Studied

Diagnosis	No. of Patients	
	Tissue	Blood
Chronic lymphocytic leukemia (B cell)	1	8
Hairy cell leukemia	1	3
Non-Hodgkin's lymphoma	18*	17†
Reactive	6	2
Lymphosarcoma cell leukemia	0	1
Hodgkin's disease	1	0

*Includes 15 B cell type, 1 T cell, 1 null cell, and 1 true histiocytic cell by immunoperoxidase studies.

†All patients had non-Hodgkin's lymphomas of demonstrated B cell type.

study was intended to compare the capabilities of κ/λ and Southern blot analysis in detecting clonal B cell proliferations, we were concerned mainly with the phenotypes of the various lymphomas. Each diagnosis was confirmed by routine histology, and the phenotype was established by immunoperoxidase staining of cryostat sections.[6] All studies were performed with the approval of the BWH human subjects committee.

κ/λ analysis. Lymphocytes were obtained by Ficoll-Hypaque centrifugation of peripheral blood or cell suspensions of tissue samples. The cells were separated into three aliquots. One was reserved for DNA analysis. The other two aliquots were labeled with rabbit heteroantisera to immunoglobulin light chains, one with κ and the other with λ. The staining procedure has been described previously.[6] Cells (1 to 2 × 10^4) from each sample were analyzed for fluorescence on a flow cytometer, and histograms were obtained by plotting relative cell number *v* log fluorescence intensity. The two curves obtained in this manner were analyzed for evidence of a monoclonal population. The studies were performed on a FACS Analyzer (Becton Dickinson Immunocytometry Systems, Mountain View, Calif). This instrument measures electronic volume and single-cell fluorescence excited by filtered light from a mercury-arc lamp.

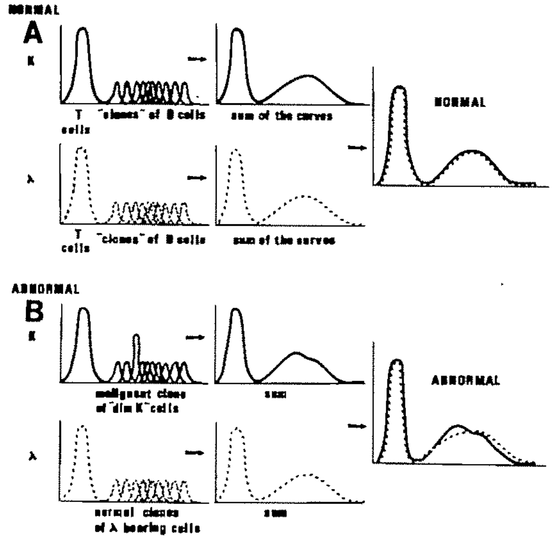

Fig 1. Detection of monoclonal B lymphocytes by "kappa-lambda" analysis; basis of the κ/λ test. Idealized fluorescence distribution curves are depicted for cells stained for surface light chains and analyzed by flow cytometry. Increasing log fluorescence intensity is shown on the horizontal axis; cell number is represented on the vertical axis. As noted in the text, each clone of B cells expresses either κ or λ light chains, but not both. The fluorescence distribution profile for each light chain is determined separately. As demonstrated here, the fluorescence distribution profile for each light chain represents a summation of the fluorescent intensity of each individual B cell clone. In normal individuals, the frequency distribution for the two light chain types is nearly identical. As shown in (A), the relative shapes and positions of the two curves are the same for both light chains. The effect of an abnormal clone of κ/λ expressing cells on the fluorescence distribution curves is demonstrated in (B). The κ distribution curve is shifted, whereas the λ light chain curve is unchanged. The difference is most obvious when the two curves are superimposed; this difference may be quantitated by computer analysis.

The basis for interpretation of histograms obtained by κ/λ analysis is outlined in Fig 1 (similar to that previously published; see ref. 6). Detection of clonal excess depends on the empiric observation that normal κ and λ histograms are identical in shape. Each curve shows a frequency distribution of fluorescence around a mean fluorescent intensity. This mean fluorescence intensity is identical for both κ-staining and λ-staining cells, and is independent of the relative numbers of cells that are positive for each light chain. As noted above, κ cells normally outnumber λ cells by a ratio of ~2:1. However, when the two curves are normalized for cell number, they become superimposable as shown in the upper panel (Fig 1). The presence of an abnormal clone (or clones) is detectable by the presence of a shift in the fluorescence distribution curves as shown in the lower panel (Fig 1). The proliferation of a clone of cells with a uniform fluorescence intensity of a single light chain causes a shift of that curve relative to the other unaffected light chain; as a result, the two curves are no longer superimposable. Differences are usually obvious on inspection of the curves. Curves were also analyzed by computer, using the Kolmogorov–Smirnov test[11] to derive a "D" value to express the differences between them. This value reflects the magnitude of the deviation of the two curves and is expressed as a percentage of the total number of cells analyzed.[6] It is independent of the number of cells staining for each light chain and provides a quantitative comparison of the two fluorescence distributions. Previous studies in this laboratory have shown that the range of D values seen in the evaluation of blood from normal individuals is 5.1 ± 3.3 (± 2 SD). A D value of 10 is thus considered to be the upper limit of normal. Occasional false-positive results have been observed in individuals with nonlymphoproliferative disorders and, rarely, in normal individuals. Consequently, studies must be correlated with appropriate clinical and histologic information.

Flow cytometry also allows fluorescence analysis of cells within selected size ranges. In some cases, cells were divided into "small" and "large" cells by selecting appropriate cell volume gates; each group was then analyzed separately for light chain distribution.[6]

DNA rearrangement analysis. High mol wt DNA was prepared from Ficoll-Hypaque gradient-purified mononuclear cells obtained as noted above. Most samples contained between 5 × 10^6 and 10^7 cells. Cells were lysed with 1% Triton X-100 in 32% sucrose at 4 °C to obtain nuclei. Nuclei were incubated overnight at 37 °C in 0.5% SDS and 0.2 mg/mL of Proteinase K. This was followed by phenol-chloroform extraction and ethanol precipitation as described by Bell et al.[12] DNA was digested with appropriate restriction enzymes, size-fractionated by agarose gel electrophoresis and transferred onto nitrocellulose paper by the method of Southern.[13] Filters were hybridized to nick-translated, ^{32}P-labeled probes of the immunoglobulin κ and λ light chain loci and were washed at 53 °C in 0.1% SDS/0.15 mol/L of NaCl–0.00 15 mol/L of Na citrate prior to autoradiography.

The probes used for Southern analysis are shown in Fig 2. The appropriate restriction sites for each probe are shown. V-J recombination in the light chain loci gives rise to an altered 5′ restriction

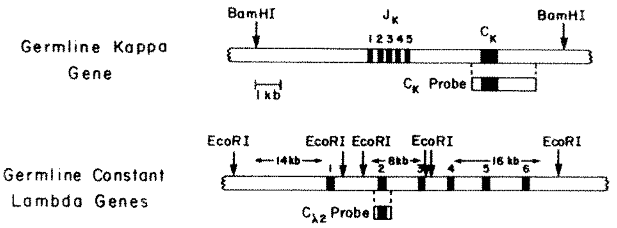

Fig 2. Probes used for DNA rearrangement studies. The restriction sites for enzymatic digestion within the light chain loci are shown. κ gene rearrangement is most easily seen using a probe derived from the κ-constant region to analyze DNA digested with Bam HI. This yields a single 12-kilobase (kb) fragment in germline DNA. λ rearrangements were demonstrated by analysis of Eco RI-digested DNA with a probe from the second constant region of the λ locus. This probe is derived from an area of Cλ2 that is highly homologous to the other constant region genes. Consequently, analysis of germline DNA typically reveals three bands of 8, 14, and 16 kb. However, the region of Cλ2 is polymorphic,[14] and the 8-kb band may be 13, 18, or, infrequently, 23 kb in length. This occasionally may make analysis of rearranged bands confusing; in such cases, granulocytes were used as a source of germline DNA for comparison and confirmation of rearrangements. The Cλ2 probe also hybridizes faintly to a 5-kb fragment that represents a pseudogene.

enzyme site and alters the size of the germline restriction fragment. Detection of one or two bands of altered size is indicative of monoclonal rearrangement of the light chain genes. Polyclonal proliferations yield small clones of varied size and do not appear as distinct bands on Southern blot hybridization. All DNAs were also probed with a probe derived from the heavy chain J region (not shown). Because heavy chain rearrangement occurs before light chain rearrangement,[8] all DNAs which displayed light chain rearrangement had also undergone alterations in their heavy chain locus. No DNAs analyzed had a heavy chain rearrangement in the absence of light chain rearrangement.

The number of λ constant region genes has been shown to vary from individual to individual.[14] Consequently, the 8-kilobase (kb) fragment diagrammed in Fig 2 may be 13, 16, or 18 kb. Because this locus has a polymorphic nature, granulocytes from patients with confusing λ gene rearrangements were run as controls. Such polymorphism does not exist in the κ locus; therefore, similar comparisons were unnecessary.

RESULTS

Detection of lymphoma cells by κ/λ and DNA restriction analysis. The ability to detect clonal excess by flow cytometry, as reflected in the D value, is correlated with the findings on DNA analysis in Fig 3. A κ/λ shift (indicated by a D value >10) was detected in 32 of 35 (92%) of cases in which monoclonal immunoglobulin rearrangements were seen on DNA analysis. The three false-negative κ/λ studies, as well as the single case in which a positive κ/λ study was not corroborated by gene rearrangement studies, will be discussed in detail below.

Characteristic results of flow cytometry and DNA rearrangement studies are compared in Fig 4. Panel A shows results obtained by each method in analysis of a lymph node involved by a κ-expressing lymphoma. There is a clearly detectable κ shift by flow cytometry, which correlates with an obvious rearrangement of the κ light chain locus seen on Southern blot analysis. The abnormal result in Fig 4A is compared with the analysis of a benign hyperplastic lymph node, in which the κ/λ curves are superimposable (D < 10), and there is no evidence of a clonal gene rearrangement.

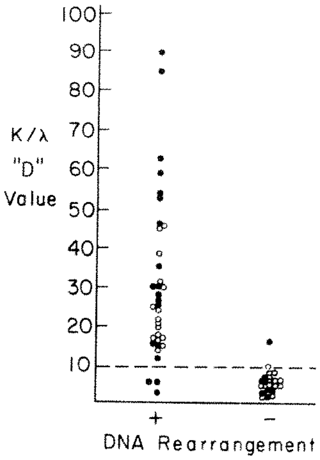

Fig 3. Comparison of results obtained by κ/λ and DNA analysis; κ/λ results, represented by the D value, are compared with the finding of the presence (+) or absence (−) of immunoglobulin gene rearrangement by restriction enzyme analysis. Using the DNA analysis as the standard, three false-negative results and one false-positive result were obtained by cytofluorometric analysis. Tissue, ●; blood, ○.

Lymphoid tissue usually contains cells of variable size. As noted above, flow cytometry allows the separate analysis of cell subpopulations of different size within a total cell population. Previous studies have shown that analyzing cells in this way allows detection of a clonal excess which may be seen only in one such subpopulation.[6] Figure 4B illustrates such a case. By flow cytometry, a clear λ shift is seen only in the large cell population, which constituted a minority of the suspended cells. This correlated with a λ locus rearrangement which was easily detected on DNA restriction fragment analysis of unsorted cells.

Correlation of blood abnormalities with tissue involvement. Tissue and blood from the same patient were obtained in ten cases as outlined in Table 2. Although only one of the 10 showed morphological evidence of peripheral blood involvement with lymphoma, κ/λ and DNA analyses were positive for lymphoma cells in four cases. All four showed identical DNA rearrangement studies in tissue and blood, confirming that shifts seen by flow cytometry correlated with the presence of circulating tumor cells.

Results of blood and tissue studies performed on one such patient are shown in Fig 4C. Flow cytometry reveals a clonal excess of λ-bearing cells in both tissue and blood. DNA analysis confirms that the clone detected in peripheral blood contains a rearrangement of the λ locus identical to that seen in the original tissue specimen.

Discrepancies between flow cytometry and DNA analysis. Previous studies have shown that 10% monoclonal B cells can be routinely detected by flow cytometry.[5] The relative sensitivities of the flow cytometric method and Southern blot analysis were directly compared in mixing studies. Varying numbers of cells from the DAUDI cell line•

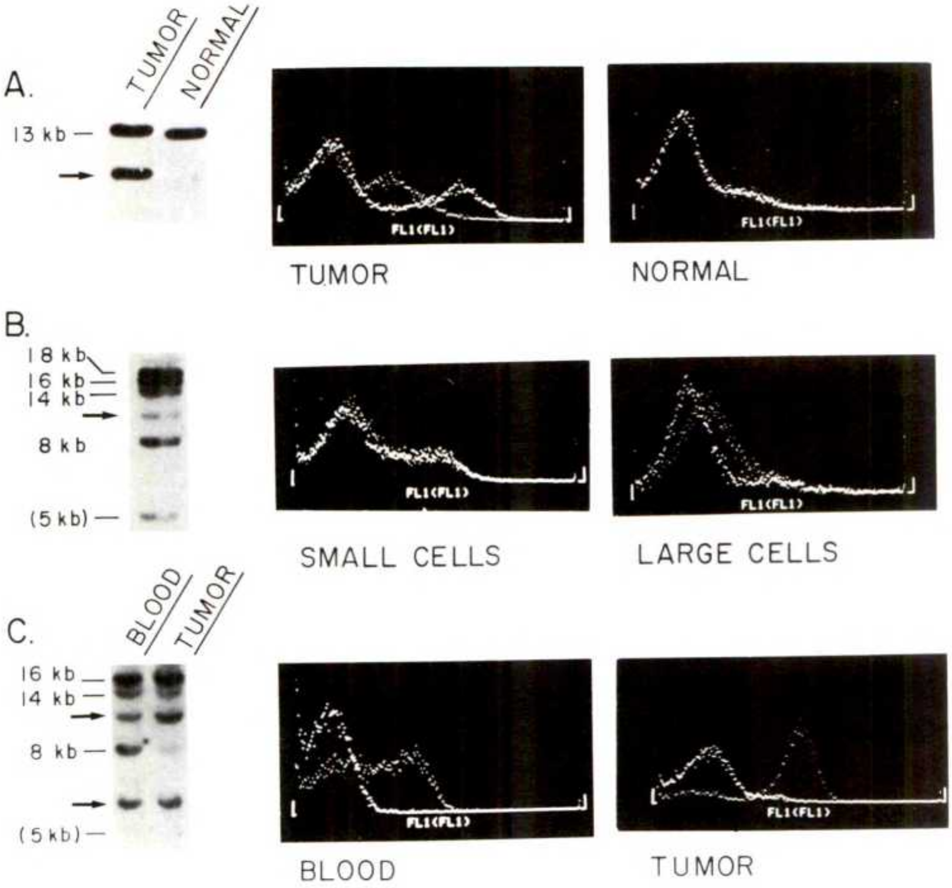

Fig 4. Characteristic DNA and κ/λ analyses. Representative examples of tissue and blood analyses are shown. (A) Typical rearrangement of the kappa light chain locus in lymphocytes from a lymph node involved with lymphoma, with the corresponding abnormal study by flow cytometry (κ, bright dots; λ, dim dots; $D = 53.7$). This study is compared with that of a benign reactive lymph node which shows no light chain abnormality by κ/λ analysis ($D < 10$) and germline κ chain genes with no clonal rearrangement. (B) Analysis of a lymph node with a smaller population of abnormal cells; κ/λ analysis was performed by selective analysis of cells by size. An abnormal clone was detected only in the large cell population ($D = 25$); the corresponding λ light chain rearrangement is seen on restriction enzyme analysis of DNA. Note the presence of the 5-kilobase (kb) fragment which, as noted above, represents hybridization to a known pseudogene. (C) Comparison of blood and tissue specimens from a patient with B cell non-Hodgkin's lymphoma (case 9, Table 2). DNA analysis shows two rearranged bands in the λ locus which are seen on analysis of both blood and tissue. The 8-kb band is very faint in the tumor DNA, consistent with rearrangement of $C\lambda 2$ involving nearly every cell. The germline band is easily seen in the blood analysis, because only a portion of the cells are tumor cells and contain the rearrangement. The DNA studies are compared with the results by flow cytometry. Again, the cells from the tumor show a single population of nearly uniform fluorescence intensity ($D = 52.4$), whereas this is seen as only a part of the cell population in peripheral blood ($D = 46.1$).

(a monoclonal B cell line that exhibits bright surface κ-staining) were mixed with normal spleen cells, and aliquots were subjected to both κ/λ and Southern blot analysis. The lowest proportion of monoclonal B cells detected by κ/λ analysis (ie, $D > 10\%$) was 5%, whereas a distinct band could still be detected on Southern blots with 1% malignant cells. This level of sensitivity of Southern blot analysis is similar to results reported by others.[11] The level of sensitivity of the κ/λ study is in fact somewhat better than previously reported; this is probably owing to the fact that the DAUDI cells exhibit particularly bright staining. Therefore, Southern blot analysis is approximately five to ten times more sensitive than κ/λ analysis in detecting monoclonal B cells. Despite this increase in sensitivity, DNA studies detected no lymphoma cells in peripheral blood samples that were not detected by the κ/λ test. The overall incidence of involvement of peripheral blood with lymphoma cells was 50% by both methods.

In only one of the three false-negative κ/λ tests on tissue samples was the sensitivity of the DNA analysis the probable reason for detecting the clonal cell population. The other two cases involved lymphoma cells with no detectable surface immunoglobulin; in both cases, the monoclonal population was well in excess of 10% of the total cells. The one false-positive case occurred in a patient diagnosed as having true histiocytic lymphoma. This diagnosis was based on immunoperoxidase and histocytochemical studies which showed that the large malignant cells lacked T cell-related or B cell-related antigens or immunoglobulin light chains, but were positive for monocyte/macrophage-related antigen (MO-2), intracellular lysozyme, and α-naphthyl acetate esterase activity.

Table 2. Comparison of Tissue and Blood From Ten Patients

Case	Diagnosis	Tissue κ/λ	Tissue DNA	Blood κ/λ	Blood DNA
1	ML-H (N + D)	λ	λ	—	—
2	ILL	κ	κ	—	—
3	DUL	κ	κ	—	—
4	PDL (N + D)	λ	λ	—	—
5	PDL (N + D)	λ	λ	—	—
6	ILL	λ	λ	λ	λ
7	ML-H (D)	κ	κ	—	—
8	CLL	κ	κ	κ	κ
9	ILL	λ	λ	λ	λ
10	CLL	λ	λ	λ	λ

ML-H, mixed lymphocytic-histiocytic lymphoma; ILL, intermediate lymphocytic lymphoma; DUL, diffuse undifferentiated lymphoma; PDL, poorly differentiated lymphocytic lymphoma; CLL, chronic lymphocytic leukemia; N, nodular; D, diffuse. All diagnoses refer to Rappaport classification, as modified to include ILL.[15]

The misassignment of light chain type to a small clone of abnormal cells is a potential error of the κ/λ test. A given clone is detectable because it has a uniform fluorescence. This fluorescence may be either brighter or dimmer than the mean fluorescence of a population of normal cells. Consequently, when the distortion of the curve is small, it is often difficult to ascertain whether the clone is of one light chain or another, although there may clearly be a clone present. This is, of course, not a problem with DNA analysis. In this study, only one sample was assigned an inappropriate light chain type by flow cytometry.

DISCUSSION

By the use of DNA restriction enzyme analysis, we have confirmed that the light chain imbalance detected by the κ/λ test is reflective of a monoclonal cell population in patients with non-Hodgkin's lymphoma. Further, we have documented that clonal excess detected in peripheral blood by flow cytometry correlates with the presence of circulating lymphoma cells identical to those present in tumor tissue.

The κ/λ test appears to be a very sensitive means of assessing cell populations for the presence of abnormal clones of B cells. In an analytic cytology lab equipped with a flow cytometer, it offers significant advantages over DNA analysis. It is less time-consuming and does not require radiolabeled probes. The κ/λ test may also be done on as few as 10^4 cells, whereas DNA studies usually require 5×10^6 cells.

In this study, we have tried to establish the circumstances under which DNA analysis offers significant advantages over κ/λ studies. There are two major reasons for false negative-results in flow cytometry analysis: technical and biologic. The studies may be inaccurate for technical reasons on several grounds: (1) the size of the clonal population may be below the limits of detectability of the κ/λ test; (2) the curves may be difficult to interpret and may lead to assignment of the incorrect light chain type; or (3) the test may be technically inadequate. In this study, few errors in diagnosis were made as a result of technique. In only one sample of the total 58 was the abnormal population detectable by DNA analysis so small as to be undetectable by flow cytometry; in one case, the light chain type was incorrectly assigned. Hence, although DNA restriction analysis is more sensitive than κ/λ analysis, it had little effect on the diagnostic accuracy of the test.

False-negative results can also arise for biologic reasons. The κ/λ test cannot detect abnormal lymphoid populations if the cells lack surface immunoglobulin, as was true in two cases studied here. In such cases, DNA analysis obviously offers significant advantages in detecting abnormal cell populations, as has been shown by others.[9]

We observed one positive κ/λ study that was not correlated with detectable DNA rearrangements. The reason for this apparent false-positive study is unclear, but there are several possibilities. Either study may have been technically at fault, although this would be surprising with a D value of 16, which suggests a significant clonal population that should be unmistakable by κ/λ analysis and easily detectable by DNA studies. Alternatively, it may reflect the biologic nature of the tumor involved. This case was diagnosed as a true histiocytic lymphoma, based on generally accepted histologic, immunologic, and histocytochemical criteria.[15] The malignant cells in this disorder phenotypically resemble normal monocytes or macrophages, and may be associated with Fc receptors with high avidity for circulating immunoglobulin.[16,17] As in this case, one would anticipate a greater nonspecific binding of κ chains than λ chains, since κ immunoglobulin is present at approximately twice the concentration of λ immunoglobulin in peripheral blood. Although cells are routinely incubated at 37 °C before staining for κ/λ analysis in order to shed cytophilic antibody, this may not have been sufficient in the presence of an avid Fc receptor. This is a potential problem with the κ/λ test, and one that has been observed in patients with M components as is seen in multiple myeloma. It is not usually seen in the presence of normal levels of immunoglobulin, presumably because the nonspecific affinity of lymphocytes for antibody is low; however, it may explain false-positive results seen in patients with high levels of circulating immunoglobulin.

In the current study, we found that 50% of the patients overall with non-Hodgkin's lymphoma of B cell type had evidence of peripheral blood involvement. This figure is somewhat less than the 80% incidence detected by κ/λ analysis recently reported.[18] There are several possible explanations for the lower rate of involvement seen in the current study. First, fewer patients were included in the present study, and inclusion of more patients may have significantly altered the proportion of positive studies. Second, the prior study included many patients with long-standing or relapsed lymphoma, whereas the present study primarily included patients at or near the time of first diagnosis. The fact that circulating lymphoma cells are present in most patients with relapsed lymphoma[18] could explain the greater incidence of positive peripheral blood findings in the earlier study.

In addition to confirming the diagnostic usefulness of the κ/λ test, our results suggest an unexpected aspect of the natural history of lymphoproliferative disease. One might have expected that use of a more sensitive test would have revealed additional cases of peripheral blood involvement undetected by κ/λ analysis. This was not what we observed, however. There were no false-negative κ/λ tests on peripheral blood as compared with DNA rearrangement studies, suggesting that the ability to invade the peripheral blood may be an intrinsic property of certain lymphomas but not of others, despite their apparent similarity by histologic examination. We did not select patients on the basis of the duration of their disease or on their exposure to chemotherapy, both of which may be crucial to the observation of peripheral blood involvement. Whether those patients showing no peripheral blood involvement later develop evidence of circulating clonal cells and whether it becomes detectable by DNA rearrangements before it is detectable by κ/λ analysis must be studied. Appropriate studies of patients with lymphoproliferative disease followed in a longitudinal fashion should aid in elucidating this further.

ACKNOWLEDGMENT

We would like to thank Dr Geraldine Pinkus for performing immunoperoxidase studies and Dr Brian Smith for his comments and assistance in preparing this manuscript.

Platelet Turnover and Kinetics in Immune Thrombocytopenic Purpura: Results With Autologous ^{111}In-Labeled Platelets and Homologous ^{51}Cr-Labeled Platelets Differ

By Anthon du P. Heyns, Philip N. Badenhorst, Mattheus G. Lötter, Henry Pieters, Paula Wessels, and Harry F. Kotzé

Mean platelet survival and turnover were simultaneously determined with autologous ^{111}In-labeled platelets (^{111}In-AP) and homologous ^{51}Cr-labeled platelets (^{51}Cr-HP) in ten patients with chronic immune thrombocytopenic purpura (ITP). In vivo redistribution of the ^{111}In-AP was quantitated with a scintillation camera and computer-assisted image analysis. The patients were divided into two groups: those with splenic platelet sequestration (spleen-liver ^{111}In activity ratio >1.4), and those with diffuse sequestration in the reticuloendothelial system. The latter patients had more severe ITP reflected by pronounced thrombocytopenia, decreased platelet turnover, and prominent early hepatic platelet sequestration. Mean platelet life span estimated with ^{51}Cr-HP was consistently shorter than that of ^{111}In-AP. Platelet turnover determined with ^{51}Cr-HP was thus overestimated. The difference in results with the two isotope labels was apparently due to greater in vivo elution of ^{51}Cr. Although the limitations of the techniques should be taken into account, these findings indicate that platelet turnover is not always normal or increased in ITP, but is low in severe disease. We suggest that this may be ascribed to damage to megakaryocytes by antiplatelet antibody. The physical characteristics in ^{111}In clearly make this radionuclide superior to ^{51}Cr for the study of platelet kinetics in ITP.

© 1986 by Grune & Stratton, Inc.

PLATELET turnover is generally regarded as normal or increased in chronic immune thrombocytopenic purpura (ITP).[1-4] However, the estimate of the extent of the increase in platelet turnover varies from a mean of 4.9 times normal[1] to 2.3 times normal.[2] This difference has been ascribed to difficulties to accurately estimate of platelet life span in ITP.[5] Because the calculation of the platelet turnover is dependent on the estimate of the platelet life span, it is clear that the result of the latter is critical.

The ^{51}Cr labeling technique[6] is used in most laboratories for the determination of platelet survival. This radionuclide has a low binding efficiency for platelets and, in ITP with severe thrombocytopenia, it is impossible to determine the life span of autologous labeled platelets by this method. ^{111}In-oxine is a superior platelet label,[7] and its high gamma photon yield facilitates quantitative imaging of the in vivo distribution of labeled platelets.[8] ^{111}In labels platelets with high efficiency, permitting kinetic studies with autologous platelets even in the presence of severe thrombocytopenia.[9,10]

We have further investigated our previous finding that platelet turnover is not always increased in ITP[9] and now relate this to the pattern of platelet sequestration in the disease. We compared the results of estimates of platelet life span with ^{111}In-oxine-labeled autologous platelets (^{111}In-AP) with that determined by ^{51}Cr-labeled homologous platelets (^{51}Cr-HP). The results differed; this influenced the estimates of platelet turnover. Turnover estimated with ^{111}In-AP was usually increased in those patients with a splenic sequestration pattern, but was decreased in patients in whom ^{111}In-AP were destroyed diffusely in the reticuloendothelial system (RES). In ITP it seems that the ^{51}Cr labeling method spuriously reduces the estimate of mean platelet survival time, and platelet turnover is therefore erroneously overestimated.

MATERIALS AND METHODS

Patients

Ten patients (patients 1 to 10) with ITP, and not on any treatment, gave informed, written consent to participate in a study approved by the Ethical Committee of the University of the Orange Free State. ITP was diagnosed on the basis of conventional clinical criteria: adult-onset thrombocytopenia of undetermined etiology, normal or increased numbers of bone marrow magakaryocytes, and the absence of a demonstrable cause of platelet destruction or utilization such as systemic lupus erythematosus, drug ingestion, or hypersplenism. Relevant patient details are given in Table 1.

Platelet Studies

Autologous platelets were labeled with ^{111}In-oxine (Radiochemical Centre, Amersham, England), fully described elsewhere.[10,11] In brief, 200 to 300 mL of blood was collected in syringes containing acid-citrate dextrose NIH formula A (ACD). Platelet-rich plasma was prepared by centrifugation and was acidified with ACD to pH 6.2–6.5. The maximum number of platelets was harvested from the blood by washing platelets from the red cell layer four times. Platelets were labeled with ^{111}In-oxine in a saline medium, resuspended in autologous platelet-poor plasma, and reinjected only if they aggregated normally with ADP. Homologous platelets were labeled with ^{51}Cr-disodiumchromate as recommended by the International Committee for Standardization in Hematology.[6] ^{111}In-AP and ^{51}Cr-HP were injected simultaneously. Contamination of the platelet product with ^{111}In or ^{51}Cr-labeled plasma proteins and red cells was measured.[6]

In vivo distribution of ^{111}In-AP was quantitated with a scintillation camera and a computer-assisted imaging system as previously described.[8,11] Whole body and region of interest (ROI) ^{111}In-radioactivity was corrected for attenuation by the geometrical mean method, and ROI activity was expressed as a percentage of whole body activity. The initial (equilibrium) radioactivity was derived by back extrapolation of linear least-squares regression analysis of data, and the final organ radioactivity was determined at the patient's own platelet survival time.

Platelet survival was estimated from whole blood specimens collected at 5, 15, 30, 45, 60, 90, and 180 minutes after reinjection of

labeled platelets and thereafter as necessitated by the rate of disappearance of platelets from the circulation.[6] Blood volume was estimated,[12] and platelets were counted by phase microscopy, or, if more than 30 × 10^9/L, with an electronic particle counter. Mean platelet survival was calculated by a nonlinear, least-squares curve-fitting technique. A computer program fitted the data to the following mathematical models: weighted mean,[6] multiple hit,[13] Dornhorst,[14] Meuleman,[15] polynomial,[16] and α order.[17] All data points lying between equilibrium or maximum blood radioactivity, and 20% of this activity, were included. Curve fitting was visually inspected with a graphics display monitor. Goodness of fit of each of the mathematical models to the data was evaluated by calculating the SD of the data points around the regression curve. There was no significant difference in the goodness of fit with these models.[18] Therefore, only the results of the mean platelet survival time estimated with the multiple hit model are presented. In all patients, the clearance of platelets from the circulation was exponential, reflected by removal of platelets after a single "hit."

Platelet recovery in the circulation at equilibrium was derived by back extrapolation of the platelet survival curve to zero time. Platelet turnover was calculated from the blood platelet count and the platelet intravascular life span.[1] The correction factor for the splenic pool was 90% divided by the percentage of ^{111}In-AP quantitated to be present in the spleen at equilibrium.

Platelets from four normal subjects were labeled with ^{111}In and ^{51}Cr as described above. Platelet subpopulations in the platelet-rich plasma were separated by density on discontinuous arabinogalactan (stractan) gradients as described by Corash et al,[19] and the radioactivity was measured. Radioactivity in the four buoyant density subpopulations was expressed as a percentage of that of the total. Mean platelet volume was measured electronically with a multichannel analyzer.[19]

Elution of Radionuclide From Labeled Platelets

The in vivo release of ^{51}Cr and ^{111}In from platelets was measured by determining the radioactivity present in platelet-poor plasma of all the specimens collected for the estimation of mean platelet life span. This radioactivity, not associated with platelets or other cells, was expressed as a percentage of ^{111}In or ^{51}Cr whole blood radioactivity at equilibrium, normalized to 100%.

Statistics

The normal distribution of the data was assessed with the Shapiro-Wilk test. Paired or unpaired data were evaluated with either the t-test for different means or the nonparametric Wilcoxon's rank sum test where appropriate. The relationship between two variables was expressed as the correlation coefficient, r, and its significance was evaluated with the t test.

The percentage SD of the platelet turnover owing to the propagation of errors introduced by the measurements of the platelet count, the platelet life span, and the estimate of the splenic platelet pool size was computed by addition in quadrature of the fractional SDs.[20]

RESULTS

Pattern of ^{111}In-Labeled Platelet Destruction

The results of quantification of organ ^{111}In radioactivity at the end of platelet life span are given in Table 2.

The patients were separated into two groups on the basis of major organ or regional ^{111}In-AP radioactivity accumulation: five with a splenic sequestration pattern, and five with a diffuse pattern of platelet destruction in the RES. The distinction was based on the percentage of ^{111}In-AP in the spleen and the liver at the end of the platelet life span. The normal spleen-liver ratio is 1.4 ± 0.6. Those patients with a spleen-liver ratio ≥ 1.4 were classified as having "splenic sequestration," and those with a lower ratio were classified as having "diffuse RES sequestration." Two patients (9 and 10) of the latter group were segregated as a subgroup because they had exceptionally low recovery values and, as compared with others in this group, had relatively long platelet survival times (Table 3).

In the group with a splenic sequestration pattern, the mean spleen ^{111}In activity was 50.8% ± 13.6%, and that of the liver was 19.4% ± 7.1%. Splenic activity was significantly higher ($P < .025$), and that of the liver was significantly lower ($P < .025$), than that of controls (t test). In the group with diffuse RES sequestration, the mean hepatic ^{111}In activity of

*The remainder is ^{111}In radioactivity located neither in the spleen nor liver. This may be regarded as approximately reflecting bone marrow activity.

42.5% ± 3.6% was significantly higher ($P < .0005$), and the mean splenic activity of 22.1% ± 9.1% was significantly lower ($P < .025$), than that of normal subjects (t test).

The ^{111}In radioactivity other than in the liver or the spleen, designated "remainder" (Table 2), varied from patient to patient and did not reflect the pattern of platelet sequestration. Although the spleen-remainder ratio was lower in the diffuse RES sequestration group, this ratio was too variable to distinguish patterns of platelet destruction.

Distribution of the In Vivo ^{111}In Platelet Activity at Equilibrium

In the group with diffuse RES destruction, mean hepatic ^{111}In activity was four times higher ($P < .005$, t test) and that of the spleen was significantly lower ($P < .025$, t test) than normal (Table 1).

Platelet Recovery, Life Span and Platelet Turnover

Blood platelet counts, mean platelet survival, recovery in the circulation, and platelet turnover measurements as determined with ^{111}In-labeled and ^{51}Cr-labeled platelets are given in Table 3.

^{111}In-labeled platelets. Patients were reinjected with a mean of 11.8 MBq ± 5.3 (319 μCi ± 143) ^{111}In, labeling 20.7 × 10^8 ± 22.1 platelets. The blood platelet counts were much higher in the splenic sequestration group than in the diffuse RES sequestration group. A greater mean number of labeled platelets and more ^{111}In was thus reinjected per patient in the splenic sequestration group. Mean recovery of platelets in the circulation of all patients was 55% ± 25%, which was somewhat lower, but not significantly so ($P > .2$), than that of normal. In patients 6, 7, and 8, with diffuse sequestration of platelets, recovery was about normal. Patients 9 and 10 had very low recoveries.

Platelet size distribution in whole blood, platelet-rich plasma, and the labeled platelet-rich saline eventually injected was determined in three patients. Although there was a loss of approximately one-half of the platelets during the isolation and labeling procedures, mean platelet volume did not change significantly: whole blood 16 ± 2 fL, platelet-rich plasma 17 ± 2 fL, and platelet-rich saline 15.5 ± 2 fL.

The mean platelet life span, range 4.3 to 65.9 hours, of ^{111}In-AP was decreased in all patients and correlated with the platelet count ($r = 0.58$, $P < .05$). The mean platelet life span of the diffuse RES sequestration group was shorter than that of patients with splenic sequestration. The results, however, were variable, and patients 9 and 10 had platelet survival times that were much longer than those of the others in this group.

Mean platelet turnover of all patients was 53 × 10^9 platelets per liter per day ± 49 (range 4 to 114). The mean platelet turnover of the splenic sequestration group was significantly higher ($P < .005$, Wilcoxon test) than normal. Platelet turnover in patients with a diffuse RES sequestration pattern was variable and was markedly low in patients 9 and 10.

^{51}Cr-labeled platelets. Patients were reinjected with a mean of 2.8 MBq ± 0.8 (84 μCi ± 15) ^{51}Cr, labeling 135.2 × 10^8 ± 57.3 platelets. Mean platelet recovery in the circulation in all patients was 51% ± 21% and, although lower than normal, was not significant ($P > .5$). The mean recovery in the circulation of the diffuse RES sequestration group was much lower than normal in patients 9 and 10.

The mean life span of ^{51}Cr-HP was shortened to varying degrees (range 1.8 to 39.6 hours), and in the patients with diffuse RES sequestration it was shorter than in patients with splenic sequestration. Patients 9 and 10 were noteworthy exceptions. Mean platelet turnover of the whole patient group was normal, 93 × 10^9 platelets per liter per day ± 80 ($P > .1$). There was, however, a significant ($P < .005$, Wil-

coxon test) difference in the mean platelet turnover of the patients with different sequestration patterns.

Comparison of Mean Platelet Survival and Turnover Measurements With ^{111}In-AP and ^{51}Cr-HP

A mean of 8.0% ± 3.1% ^{51}Cr and 7.5% ± 6.5% ^{111}In was present in the plasma in which the labeled platelets were suspended. Contamination of labeled platelets with labeled red cells was low; 1.3% ± 1.1% and 1.1% ± 1.6% for ^{51}Cr and ^{111}In, respectively.

Mean survival of ^{111}In-AP was 26.3 hours ± 19.7, and that of ^{51}Cr-HP was 16.8 ± 13 hours. This difference was significant ($P < .005$, Wilcoxon test). This difference was evident whether women patients had had previous pregnancies or not. The difference influenced the estimate of mean platelet turnover: with ^{111}In-AP it was 53 × 10^9 platelets per liter per day ± 49, which was significantly ($P < .005$, Wilcoxon test) lower than the 93 × 10^9 platelets per liter per day ± 80 as estimated with ^{51}Cr-HP.

Labeling of Platelet Subpopulations

Labeling efficiencies with ^{111}In and ^{51}Cr of density-dependent platelet subpopulations separated on a stractan gradient, were similar ($P > .2$; *t*-test) (Table 4).

Plasma Radioactivity

The ^{111}In and ^{51}Cr radioactivity in platelet-poor plasma was measured for the duration of the platelet life span. The changes in radioactivity in plasma during the first nine hours after reinjection of labeled platelets are illustrated in Fig 1. ^{51}Cr activity was higher than that of ^{111}In ($P < .005$, *t* test) throughout the life span of the platelets, but the difference was more striking in the first few hours after reinfusion of labeled platelets.

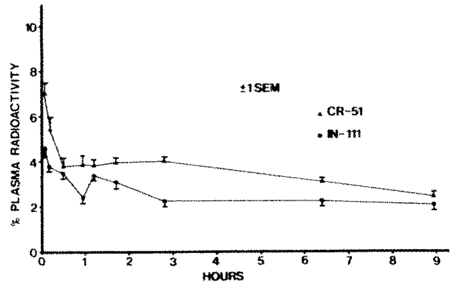

Fig 1. Plasma ^{111}In and ^{51}Cr radioactivity of blood samples taken to measure mean platelet survival time. ^{51}Cr plasma activity was significantly ($P < .005$) higher than that of ^{111}In. This is presumably due to in vivo elution of the label.

DISCUSSION

It has generally been stated that platelet turnover is increased in patients with ITP, and that this increase is especially evident when the blood platelet count is <50 × 10^9/L,[1-5] but not all authors agree.[9,21-24] A major difficulty thwarting the clarification of the problem is the inaccuracy of the measurement of platelet turnover in ITP. In ITP, it is difficult to measure three of the variables used in calculating platelet turnover: mean platelet life span, recovery of platelets in the circulation, and the blood platelet count. We have exploited the superior physical characteristics of ^{111}In and its high platelet labeling efficiency to minimize these difficulties. This radionuclide makes it possible to determine platelet survival and to image the in vivo distribution of autologous platelets quantitatively even in the presence of severe thrombocytopenia.[9,10] In addition, the size of the splenic pool may be determined accurately with quantitative imaging.[11,25]

It is convenient to consider our findings in the context of the in vivo distribution of the labeled platelets. In our previous study, we divided patients with ITP into three groups on the basis of the sites of platelet destruction: splenic, hepatic, and diffuse RES sequestration.[9] Because this grouping was somewhat arbitrary and there was considerable overlap, we have now grouped the hepatic and diffuse RES sequestration patients together. The division between the two major groups was based on the spleen-liver ratio and was clearcut. Although they had low spleen-liver ratios, patients 9 and 10 had low recovery values and relatively long mean platelet survival times; we have therefore separated them as a subgroup. Most of the platelets not destroyed in the liver or spleen, ie, the remainder, are sequestrated in the bone marrow.[8,9,25] Although the spleen-remainder ratio was lower in patients with diffuse RES platelet sequestration, this ratio neither identified another pattern of sequestration nor improved on the discriminatory value of the spleen-liver ratio. We observed a relationship between the blood platelet count and the sequestration pattern. Splenic sequestration was seen in patients with a relatively high platelet count, whereas diffuse RES sequestration occurred in those with low platelet counts. We therefore agree that the pattern of platelet sequestration is related to the severity of the disease.[4]

Table 4. Percentage of Distribution of Normal Platelets of Different Densities Labeled With ^{111}In and ^{51}Cr

	Stractan Density (g/mL) 1.084		Stractan Density (g/mL) 1.071		Stractan Density (g/mL) 1.066		Stractan Density (g/mL) 1.062

Mean ± 1 SD	50.5 ± 2.1	50.7 ± 1.9	26.9 ± 4.2	28.6 ± 4.9	15.5 ± 4.7	15.2 ± 3.8	7.0 ± 3.4	5.5 ± 3.1

In normal subjects, mean platelet survival estimated with ^{111}In and ^{51}Cr as cell labels is similar.[26] We now demonstrate that in ITP the survival of ^{111}In-AP is significantly longer than that determined simultaneously with ^{51}Cr-HP. This agrees with our previous view[8] and has recently also been found in moderately thrombocytopenic patients with ITP studied with ^{111}In- and ^{51}Cr-labeled autologous platelets.[27] It is unlikely that the discrepancy is due to isoimmunization because previous pregnancies or blood transfusions were not relevant in our patients. Neither is varying use of homologous *v* autologous platelets the explanation.[27]

It has been shown in vitro that small molecules such as ^{51}Cr are more readily lost from platelets than is ^{111}In-binding protein.[28] Our results, although not conclusive, suggest that this may occur in vivo. Plasma activity of ^{51}Cr was significantly higher than that of ^{111}In, especially during the early period after reinjection of labeled platelets. The in vitro contamination of labeled platelets with ^{51}Cr or ^{111}In in plasma was similar; therefore, the infusion of free radionuclide does not explain the difference in platelet survival times with the two isotopes. However, it is possible that the two radionuclides may be bound to different plasma proteins. This would affect the clearance rates of the isotopes from the circulation and is an alternative explanation for the results in Fig 1.

We also investigated the possibility that ^{51}Cr and ^{111}In do not label the circulating platelet population uniformly or to the same extent. Misleading platelet survival information could be obtained if one of the isotopes had a greater affinity for a specific platelet subpopulation. This is unlikely because ^{111}In and ^{51}Cr radioactivities were distributed equally in the platelet subpopulations separated on stractan. In addition, a select population of platelets with a different mean volume from that of whole blood platelets was not lost during harvesting and labeling.

Finally, platelets remaining in the circulation in ITP after a steady state has been reached may be relatively resistant to antibody injury. Autologous labeled platelets may thus have a longer mean survival time in the patient than does the heterogeneous platelet population of a normal donor. This has a precedent in autoimmune hemolytic anemia.[29] Our study has not excluded this possibility.

The estimate of the size of the splenic platelet pool will also influence the calculation of platelet turnover. The size of the splenic pool is considered normal in ITP,[26] but the estimates of the percentage of recovery of labeled platelets in the circulation vary from low[2] to near normal.[1] This discrepancy may be owing to the methods used in determining recovery. It is not clear whether it is more appropriate to estimate recovery by extrapolation of blood radioactivity values to zero time (as in ref. 1 and our study) or by measuring blood radioactivity at equilibrium.[2] Our data do not answer this question, but demonstrate that the estimate of recovery may be influenced by the pattern of platelet sequestration. If one assumes that the only significant exchangeable platelet pool is in the spleen, percentage of platelet recovery in the circulation and splenic radioactivity should total ~100%. In normal subjects, mean platelet recovery is 61% ± 12%, and at equilibrium 31.1% ± 6.1% of ^{111}In-labeled platelets are present in the spleen.[11] This was not so in ITP. In patients with a splenic sequestration pattern, mean recovery was 65.8% ± 11.8%, and the size of the splenic pool was estimated at 32.8% ± 9.8%, resembling that of normal subjects. In contrast, the group of patients with diffuse RES platelet sequestration had a mean ^{111}In-AP recovery of 44% ± 31% and a mean spleen pool of 21.4% ± 8.6%. This deficit may readily be accounted for by the very high liver ^{111}In-AP activity at equilibrium. It seems likely that in patients with diffuse RES sequestration of platelets many platelets are destroyed in the liver before attainment of equilibrium between the blood and splenic platelet pools.

All of the above factors should be taken into account when considering platelet turnover in ITP. We estimate that the propagation of errors introduced by the determination of the parameters used to calculate platelet turnover has a percentage SD of 26% in patients with a blood platelet count of 10×10^9/L. There was also marked variation from patient to patient as reflected by the large SDs. Therefore, it is clear that the physiological interpretation of results of kinetic studies in these patients should be guarded.

Notwithstanding our reservations, our results indicate that platelet turnover calculated with ^{111}In-labeled autologous platelets identifies a subset of patients with low platelet turnover, and that these patients have more severe disease as reflected by a low platelet count and diffuse RES sequestration of platelets. Platelet turnover measured with ^{111}In-AP was high in all patients with a splenic sequestration pattern. The mean increase was 2.2 times that of normal (range 1.2 to 3.0). In contrast, mean platelet turnover was decreased (mean 0.4 times normal) in all patients with diffuse RES sequestration of ^{111}In-AP, and especially so in patients 9 and 10. Mean platelet turnover estimated with ^{51}Cr-HP was significantly higher in both patient groups than platelet turnover measured with ^{111}In-AP. Our results are thus not in accordance with studies in which platelet turnover was found to be either normal or increased in ITP[1-4,30] but tend to agree with those of recent studies with ^{51}Cr-labeled platelets[21,23] and ^{111}In-labeled platelets.[9,24,27]

These results may be related to other findings difficult to reconcile with the concept that platelet production is always increased in ITP. There is some evidence that antiplatelet antibodies may damage megakaryocytes and impair megakaryocytopoiesis. Rolovic et al[31] have shown that megakaryocytopoiesis in rats with thrombocytopenia induced with heteroimmune antiplatelet serum is markedly altered. They demonstrate coexistent platelet destruction and defective thrombopoiesis in this experimental model of ITP. It has also been shown that the antiplatelet antibody of ITP binds to both platelets and megakaryocytes[32,33] and may impair platelet production at the level of the mature megakaryocyte.[23] It therefore seems plausible that the low platelet turnover demonstrated in our patients may be owing to antibody-mediated injury to the megakaryocytes. The more severe impairment of thrombopoiesis seen in patients with diffuse RES sequestration of platelets may be related to the finding that this destruction pattern typical of severe disease is owing to greater amounts of antibody bound to platelets.[34] It seems plausible that megakaryocytes may be damaged in such patients with high antibody levels.

It it evident that the application of the techniques of labeling autologous platelets with ^{111}In and the technology of quantification of the in vivo distribution of labeled platelets have provided new insights into the pathogenesis of ITP. However, they have also exposed new problems reflecting the complexities of the disease and the difficulties associated with the interpretation of the data.

Purified Radiolabeled Antithrombin III Metabolism in Three Families With Hereditary AT III Deficiency: Application of a Three-Compartment Model

By E.A.R. Knot, E. de Jong, J.W. ten Cate, A.H.C. Iburg, Ch.P. Henny, T. Bruin, and J. Stibbe

Purified human radioiodinated antithrombin III (^{125}I-AT III) was used to study its metabolism in six members from three different families with a known hereditary AT III deficiency. Six healthy volunteers served as a control group. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and crossed immunoelectrophoresis (CIE) showed the purified AT III to be homogenous. Amino acid analysis of the protein revealed a composition identical to a highly purified internal standard. The specific activity was 5.6 U/mg. Analysis of plasma radioactivity data was performed, using a three-compartment model. Neither plasma disappearance half-times nor fractional catabolic rate constants differed significantly between patients and control subjects. The mean absolute catabolic rate in the patient group was significantly lower than that of the control group at 2.57 ± 0.44 and 4.46 ± 0.80 mg/kg/day, respectively. In addition, the mean patient α_1-phase, flux ratio ($k_{1,2}$ and $k_{2,1}$) of the second compartment α_2-phase and influx ($k_{3,1}$) of the third compartment were significantly reduced as compared with control values. It has been tentatively concluded that the observed reduction in the second compartment may be caused by a decrease in endothelial cell surface binding.

ANTITHROMBIN III (AT III) has been shown to be a major inhibitor of activated serine proteases.[1,2] A high incidence of thromboembolic disease has been recognized in individuals with a hereditary deficiency of this inhibitory protein.[3,4] The causal mechanism of the hereditary AT III deficiency may be based on a singularly decreased synthetic capacity, increased consumption within the vascular compartment by ongoing insufficient inhibition of thrombin generation, differences in the distribution of the proteins over various compartments, or a combination of the three mechanisms.

To elucidate the influence of these hypotheses on the actual cause of this deficiency, metabolic studies with highly purified radiolabeled AT III are required. Metabolic studies thus far performed have provided insufficient information. In one study, plasma disappearance half-times of transfused human AT III concentrate were calculated.[5] The corrective effect of a possibly increased consumption of AT III by normalization of AT III plasma levels is a theoretical pitfall in this study. Other studies involving a total of four AT III-deficient patients used either small amounts of radiolabeled AT III concentrates with a low specific activity (3.2 U/mg protein),[6] a preparation with an unfavorable activity-antigen ratio of 0.5,[7] or an autologous preparation with unknown specific activity.[8] Preparations with a higher specific activity, 5.75 U/mg protein, were used by other researchers,[9] but in this case, studies were performed on normal subjects and patients with deep venous thrombosis. Theoretically, the maximum specific activity that can be obtained in purified AT III preparations is 7 U/mg protein. Specific activities influence the plasma disappearance half-times as reflected in the shorter half-life found in the study using the highly purified AT III preparation (67.2 ± 6.2 hours),[9] when compared with the studies using preparations with either unspecified or lower specific activities (81.6 to 115.2 hours).[6,7] Contamination with even trace amounts of proteins with a longer plasma disappearance half-time (eg, albumin) may cause considerable error.[10]

The present study therefore describes the AT III metabolism in six patients with a known hereditary AT III deficiency, using highly purified radiolabeled AT III (5.6 U/mg). Data analysis was based on a three-compartment model.

MATERIALS AND METHODS

Subjects. The study group was comprised of six patients with a hereditary AT III deficiency; patients were from three different families. The control group consisted of six healthy subjects (Table 1). Laboratory investigations in all individuals showed no proteinuria or abnormal liver functions. Of four members of the patient group, three had a medical history of thromboembolism demonstrated by V/Q scanning and/or impedance plethysmography. These patients received oral anticoagulant therapy at the time of the study. The biological and antigenic activity measured by chromogenic and immunological methods, respectively, showed reduced levels in all patients (Table 1). Crossed immunoelectrophoresis (CIE) of their plasma against the specific human AT III antiserum in the presence of heparin revealed normal AT III peak electrophoretic mobility.

The study was approved by the medical ethical and research committees, and informed consent was obtained from each individual before entry into the study. The investigation was carried out according to the declaration of Helsinki-Tokyo.

Laboratory procedures. Venous blood was collected in plastic tubes containing either solid dipotassium EDTA (1.5 mg/1 mL of blood) or trisodium citrate dihydrate (3.2 mg/1 mL of blood) using a 20-g Wasserman needle. Plasma was prepared by centrifugation at 1,700 g for ten minutes and was rendered platelet-poor by a second run at 12,000 g. Plasma samples were stored in small aliquots at −70 °C. Reference pooled plasma was obtained from 40 healthy volunteers (sex ratio 1:1). Biologic AT III activity was measured using a chromogenic substrate method.[11] Antigenic activity was measured using 1% agarose containing 20 μL of antiserum/1 mL.[12] Both rabbit anti-human AT III antiserum and total antiserum were purchased from Behringwerke A.G., Marburg Lahn, FRG. Standard curves were prepared using stepwise dilutions of citrated pooled plasma. Electrophoresis of these samples (5 μL) was performed at 10 V/cm per plate for 16 hours; subsequently, they were washed in saline and in distilled water, and were then dried and stained with Coomassie brilliant blue. CIE was performed according to Laurell,[13] as modified by Sas et al.[14] In the first dimension, 5 μL of plasma was

electrophoresed at 15 V/cm with heparin (Thromboliquine, Organon, Oss, The Netherlands) in both buffer and agarose (16.6 U/mL). Electrophoresis in the second dimension took place for 12 to 14 hours at the same voltage with the agarose containing 20 μL AT III antiserum permillilter.

Purification of AT III. As a basic substance, human AT III concentrate (albumin free-DcA-107) obtained from KabiVitrum, Stockholm, Sweden, was used. This concentrate was previously used in other studies.[7] However, CIE of the concentrate showed several contaminants that potentially could interfere with the survival study. The concentrate was therefore further purified, using a heparin sepharose chromatography column (2.5 × 45 cm). The non-heparin binding fraction was removed by washing with phosphate-buffered saline (PBS) (pH 7.4). The heparin binding fraction was eluted with 1.5 mol/L of NaCl in PBS (pH 7.4). Subsequent sodium dodecyl sulfate-polyamide gel electrophoresis (SDS-PAGE)[15] using a Coomassie brilliant blue stain revealed one band with a mol wt of 67,000 daltons (Fig 1A). CIE of this purified AT III against whole human antiserum showed one precipitation arch (Fig 1B). The specific heparin cofactor activity was 5.6 U/mg. Amino acid analysis (D. Collen, Leuven, Belgium) showed a composition similar to that of a highly purified internal standard preparation (Table 2).

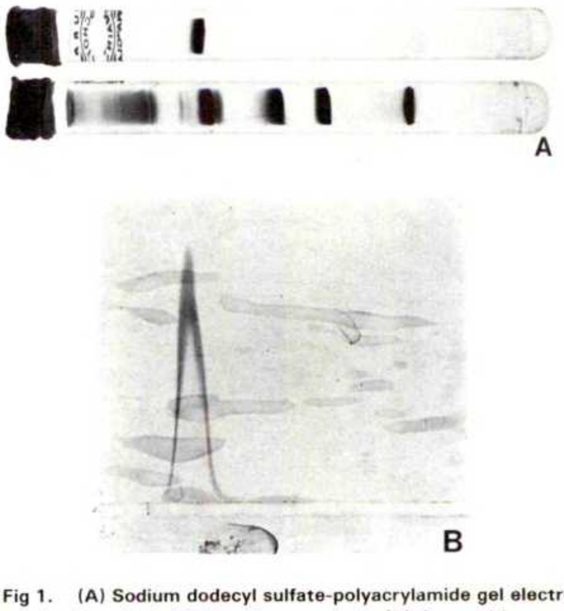

Fig 1. (A) Sodium dodecyl sulfate-polyacrylamide gel electrophoresis of purified AT III and a standard. (B) Crossed immunoelectrophoresis of purified AT III in agarose containing whole human antiserum.

Preparation of radioactive tracer and in vitro characterization of ^{125}I-AT III. The purified AT III was radiolabeled with ^{125}Iodine using the Iodogen method.[16] ^{125}I-AT III was separated from the free iodine by gel filtration on Sephadex G 25. The ^{125}I-labeled tracer was subsequently applied to a heparin sepharose Column (1 × 8 cm). The non-heparin binding fraction was removed by washing by PBS (pH 7.4) and the heparin binding ^{125}I-AT III was eluted with 1.5 mol/L of NaCl in PBS (pH 7.4). The fractions were pooled, isotonized with sterile distilled water, treated with millipore filtration (0.45 μm), and stored in small aliquots at −70 °C. A specific radioactive activity of 1.3 to 4 μCi/1 mg AT III was obtained.

Each batch was tested and found to be negative for HbsAg (Ausria II) and endotoxins.[17] CIE[18] of a mixture of human plasma and ^{125}I-AT III against rabbit anti-human serum (Behringwerke), when stained for protein, showed a single precipitation arch. Its mobility was identical to that of the radioactivity peak depicted on autoradiography (Kodak XAR, Eastman Kodak Co, Rochester, NY).

Gel filtration (Sephadex G100) of a mixture of ^{125}I-AT III and normal human plasma showed a single radioactivity peak; elution patterns, as well as AT III antigenic and biological activity, were identical. The biological specific activity of the preparations was

unchanged after the labeling procedure. Turnover data obtained with this preparation could thus be assumed to reflect that of the total body AT III pool.

Turnover studies. Before injection and, subsequently, once daily throughout the course of the study, each subject received iodine capsules (100 mg) to avoid thyroidal uptake of ^{125}Iodine. Ten μCi ^{125}I-AT III was injected intravenously (IV) and blood samples were taken at 10, 30, and 60 minutes; at 2, 4, and 6 hours; and subsequently twice daily for 6 days. Urine was collected at 24-hour intervals. At the end of the study, the samples were counted for radioactivity using a Beckmann gamma counter (Beckmann Instruments, Inc, Fullerton, Calif).

Trichloroacetic acid precipitation was performed on both plasma and urine samples. Less than 2% of the radioactivity was recovered in the plasma supernatant, whereas no precipitable ^{125}I was found in the urine samples.

Tracer data. The initial values were obtained by curve-peeling on a home computer using a three-compartment model[19] and were then further analyzed on a VAX 11/750 computer by means of the program BMDP3R (V 2.1) (© 1979, the Regent of the University of California). Curve fitting as to the plasma radioactivity data was performed by a sum of three exponential terms:

$$(X(t) = A_1e^{-\alpha_1 t} + A_2e^{-\alpha_2 t} + Be^{-\beta t}.$$

The fractional catabolic rate constant ($k_{1,0}$), the transcapillary flux ratio's and plasma disappearance half times were calculated as follows:

$$k_{1,0} = 1/(A_1/\alpha_1 + A_2/\alpha_2 + B/\beta)$$

$$\begin{aligned} k_{2,1} = \tfrac{1}{2}|B \cdot (\alpha_1 - \beta) + A^2(\alpha_1 - \alpha_2) + \beta + \alpha_2 \\ + \sqrt{(\{B \cdot (\alpha_1 - \beta) + A_2(\alpha_1 - \alpha_2) + \beta - \alpha_2\}^2} \\ + 4A_2(\alpha_2 - \beta)(\alpha_1 - \alpha_2))| \end{aligned}$$

$$\begin{aligned} k_{3,1} = \tfrac{1}{2}|B \cdot (\alpha_1 - \beta) + A_2(\alpha_1 - \alpha_2) + \beta + \alpha_2 \\ - \sqrt{(\{B \cdot (\alpha_1 - \beta) + A_2(\alpha_1 - \alpha_2) + \beta - \alpha_2\}^2} \\ + 4A_2(\alpha_2 - \beta)(\alpha_1 - \alpha_2))| \end{aligned}$$

$$k_{1,2} = (k_{2,1} - \beta) \cdot (k_{2,1} - \alpha_2) \cdot (k_{2,1} - \alpha_1)/(k_{2,1} \cdot (k_{3,1} - k_{2,1}))$$

$$k_{1,3} = (k_{3,1} - \beta) \cdot (k_{3,1} - \alpha_2) \cdot (k_{3,1} - \alpha_1)/(k_{3,1} \cdot (k_{2,1} - k_{3,1}))$$

The plasma half-disappearance time = $\ln(2)/\beta$. The absolute catabolic rate constant (synthesis) is calculated from the fractional catabolic rate, the blood volume, and the AT III plasma antigen levels.

Statistical analysis. The Wilcoxon test for independent samples was used to establish the incidence of abnormal values outside the 95% confidence interval of the respective control values. A *P*-value of ≤.05 was considered significant. Results have been expressed in means ±1 SD.

RESULTS

The metabolic data of the patients and control subjects are depicted in Table 3. The following results were obtained in

the control group: the plasma half-life was 61.4 ± 7.0 hours with a fractional catabolic rate of 0.626 ± 0.101 of the plasma pool per day. The plasma AT III concentration was 15.64 ± 1.41 mg/100 mL. The absolute catabolic rate was 4.46 ± 0.80 mg/kg/day. In the patient group, the following metabolic data were obtained: a plasma disappearance half-time of 66.9 ± 7.8 hours with a fractional catabolic rate of 0.676 ± 0.118 of the plasma pool per day; when compared with the control group, no intergroup differences were found. The plasma AT III concentration was 8.94 ± 0.62 mg/100 mL with an absolute catabolic rate of 2.57 ± 0.44 mg/kg/day, which was significantly reduced in comparison with control values ($P < .005$).

The α_1-phase was significantly lower when compared with the control values 0.487 ± 0.247 and 1.668 ± 0.979, respectively ($P < .005$).

The influx and efflux ($k_{2,1}$ and $k_{1,2}$) of the second compartment (0.337 ± 0.228 hour^{-1} and 0.0745 ± 0.0379 hour^{-1}, respectively) were significantly reduced when compared with the control values (1.45 ± 0.855 hour^{-1} and 0.207 ± 0.144 hour^{-1}, respectively) ($P < .005$ and $P < .01$). The α_2-phase and influx ($k_{3,1}$) of the third compartment (0.0509 ± 0.0068 and 0.0267 ± 0.0084 hour^{-1}, respectively) were also reduced as compared with the control values (0.0711 ± 0.0146 and 0.0363 ± 0.0075 hour^{-1}, respectively ($P < .005$ and $P < .05$).

DISCUSSION

Because it has been recognized that the hereditary AT III deficiency is associated with an increased risk of the development of thromboembolic complications, the interest in the AT III metabolism has expanded.[3,4] Following the introduction of purification by heparin affinity chromatography,[20] AT III concentrates have been made available for therapeutic use. Recently, these concentrates have been tested[21] and have been found to be impure, containing substantial amounts of altered AT III molecules in addition to other proteins.

CIE of the basic purified AT III used in another metabolic study[6] showed contaminations with many other trace amounts of proteins. Because of the presence of these contaminants, these metabolic studies using other coagulation proteins and/or antithrombin III should be critically reviewed.[10] Albumin contamination of AT III concentrates used in metabolic studies may influence the results of the plasma disappearance half-time of AT III due to the long disappearance half-time of the contaminant proteins (22.5 days).[22] Metabolic studies using such concentrates and/or roughly purified AT III are thus not a true reflection of the in vivo biological behavior of AT III. For the present study, we therefore further purified the AT III concentrate by repeated affinity chromatography until a protein with a specific activity of 5.6 U/mg was obtained. Its purity was further analyzed by CIE against total human antiserum and by amino acid composition analysis, showing a single precipitation arch and revealing a pure AT III preparation, respectively. For data analysis, a three-compartment model was used (previously described[23]), which was better than a two-compartment model. This was also found by other investigators who studied AT III metabolism in an animal experimental model.[24] The results of the plasma disappearance half-time in patients (66.9 ± 7.8 hour) did not significantly differ from the control group value. These half-lives, however, were shorter in those found in studies using radiolabeled AT III concentrates,[6,7] but comparable to the half-lives found by Collen et al.[9] The patient mean fractional catabolic rate was not significantly different from control values, indicating that there is no consumption in the central compartment. This included the two patients who did not receive oral anticoagulant therapy. When compared with the rates of the control group, the absolute catabolic rate (synthesis) was significantly reduced in all patients. In addition, a slower α_1-phase and a reduced flux ratio ($k_{1,2}$, $k_{2,1}$) of the second compartment were found in the patient group. The α_2-phase and influx ($k_{3,1}$) of the third compartment were also slower as compared with the control subjects.

Translation of the mathematical analysis of various compartments into the biological model revealed an association between the first compartment and the intravascular compartment. Taking into consideration that the equilibrium of the third compartment was reached after ~25 hours, this may be biologically identified as the extravascular compartment. If so, reduced $k_{3,1}$ shows a smaller efflux from the extra vascular compartment into the vascular compartment.

Translation of the second compartment into any physiological compartment may still be speculative, although some arguments are indicative of the possible binding of AT III to endothelial cells.[25] This is further substantiated by the fact that apparent plasma volumes calculated from isotope dilution measurement (dose divided by radioactivity of the blood samples after ten minutes) are substantially larger than the real plasma volumes, indicating that a proportion of the injection protein may have been rapidly transferred from the circulation to a non-plasma vascular compartment.[24] This non-plasma vascular compartment may be associated with the AT III fraction bound to the endothelial AT III cofactor that has been found on the endothelial surface.[24-26] The hypothetical association with circulating blood cells has previously been excluded.[24]

The hypothesis that the second compartment may be associated with endothelial binding sites can be supported by findings from our previously performed metabolic studies in patients with cirrhosis of the liver.[27] In these patients (without ascites), a significantly increased α_1-phase was found, and a higher apparent distribution volume correlated well with the severity of disease (enlargement of liver and spleen, demonstrated by scintigraphy). In patients with a hereditary AT III deficiency, the slower rate of reaching equilibrium of the second compartment may be explained by two hypotheses: (1) an increased second compartment, possibly based on an increased number of AT III cofactor binding sites; and (2) a decreased binding potential of AT III to these binding sites.

In conclusion, in patients with a hereditary AT III deficiency, the absolute catabolism takes place at a lower rate. There are no signs of AT III consumption within the intravascular compartment. The AT III plasma disappearance half-time was normal. A slower rate was found at which the equilibrium of the second compartment (endothelial binding) is reached as well as a slower influx to the vascular compartment from the extravascular compartment.

Fetal to Adult Hemopoietic Cell Transplantation in Humans: Insights Into Hemoglobin Switching

By Th. Papayannopoulou, B. Nakamoto, F. Agostinelli, M. Manna, G. Lucarelli, and G. Stamatoyannopoulos

A 2-year-old boy with refractory acute leukemia (ALL) was transplanted with liver cells from twin fetuses of an 18-gestational-week age. Regeneration of hemopoietic cells was evident during the second week following transplantation when a cellular, predominantly erythroid, marrow was present. Studies of bone marrow and peripheral blood cells obtained 21 days posttransplant showed that bone marrow and peripheral blood BFU-E-derived erythroblasts displayed typical fetal patterns of globin chain synthesis ($\gamma/\gamma + \beta$ ratios: 0.87 to 0.98). In addition, all of the individually analyzed erythroid clones displayed a fetal type of globin program, suggesting that the presence of rare, partially switched clones was unlikely. Additional evidence supported the fetal phenotype of these progenitors. The iI expression of culture-derived erythroblasts was typical for fetal erythroid cells. As in fetal cells, fetal sheep serum influenced neither the globin nor the iI phenotypes, and the growth characteristics were as those observed in fetal liver cultures. That these fetal progenitors matured in vivo and produced cells with a fetal program was shown by the pattern of globin biosynthesis in bone marrow cells and peripheral blood reticulocytes ($\gamma/\gamma + \beta$ ratios: 0.85 to 0.95) at days 14 and 21 posttransplantation. These results indicate that the transplanted fetal cells, in spite of their proliferation and differentiation in the environment of the recipient, continued to express during the early posttransplantation period fetal patterns of globin, surface antigenic determinants, and growth and response to environmental modulation. The observations in this patient support the notion that hemoglobin switching is primarily controlled by a mechanism intrinsic to the stem cell.

© 1986 by Grune & Stratton, Inc.

TRANSPLANTATION of hemopoietic cells into recipients of a different developmental stage can be used as a model system for studying the cellular control of hemoglobin switching.[1-6] Transplantation of fetal liver cells into adult recipients, carried out in sheep, has provided insights as to whether the stem cell or the environment is primarily responsible for the control of hemoglobin switching.[1,2,5,6] In humans, transplantation of fetal liver cells has been used for experimental treatment of children with aplastic anemia or leukemia.[7-9]

We had the opportunity to study the erythroid cells of a 2-year-old leukemic child who was transplanted with a suspension of cells from the liver of second trimester human twin fetuses. Globin expression was studied in the in vivo erythroblasts and reticulocytes of the recipient. In addition, in the present study, the globin programs, growth pattern, and expression of the iI antigenic system were assessed in erythroid colonies grown from the recipient's bone marrow and peripheral blood samples. Our analyses suggest that the recipient's cells expressed, both in culture and in vivo, a typical fetal program of globins. The iI determinants and growth characteristics were those expected for fetal progenitors. These results suggest that the donor cells continued to express a genuine fetal phenotype while proliferating and differentiating in the recipient's environment.

MATERIALS AND METHODS

The patient was a 2-year-old boy who, at the age of 10 months, was diagnosed as having acute lymphocytic leukemia (ALL). He was transplanted after second remission following standard preparative regimens.[7,8] The donor cells were from twin fetuses of an estimated 18-week gestational age. He received red cell and platelet support in the posttransplant period. A bone marrow sample, obtained 14 days following transplantation, provided morphological evidence of trilineage engraftment. The patient died at the 27th posttransplant day from sepsis.

Blood counts (HCT, red cells, WBC, platelets, reticulocytes) were determined at frequent intervals (Fig 1). Fetal hemoglobin and F-cell numbers were evaluated on day +21. Globin biosynthesis in peripheral reticulocytes or in bone marrow cells, after incubation with ^{3}H-leucine, was carried out on day +14 and +22. Bone marrow and peripheral blood samples obtained on posttransplant day 21 were sent to Seattle for the studies described below.

Buffy coat bone marrow cells and nonadherent mononuclear cells from peripheral blood were plated in plasma clot and methylcellulose cultures. The composition of the media was as described before,[10] with the exception that in some plates fetal sheep plasma or serum[11] was substituted for the fetal calf serum (FCS). Growth was monitored by inspection of the cultures at regular intervals.

For studying the cellular expression of globins in the in vitro-derived clones, plasma clot cultures at days 8 and 9 were double-labeled with anti-γ and anti-β chain monoclonal antibodies,[12] using previously described immunofluorescent staining procedures.[13] For measuring globin biosynthesis in clones maturing sequentially in culture, a large number of mature erythroid clones (over 100 per time point and culture condition) were lifted from the plates, pooled, and incubated with ^{3}H-leucine at any given time. Lysates from the incubated colonies were used for globin chain isoelectric focusing and measurements of globin chain biosynthetic ratios as described before.[14] For measuring globin biosynthesis in individual erythroid bursts, each burst was placed in a microfuge tube, the incubation mixture (containing leucine-free media and ^{3}H-leucine) was added, and the lysates from incubated cells were used for globin chain isoelectric focusing.

To study the expression of i and I antigens in culture-derived erythroblasts, colonies were lifted from the plates. After the cells were dispersed, they were reacted either with anti-i (anti-i Den) serum or anti-I (anti-I Ma) serum and counterlabeled with anti-human IgM-fluorescein isothiocyanate (FITC). Fluorescent intensity of the labeled cells was assessed with both microscopic examination of the preparations and with analysis of fluorescent profiles using a FACS (Ortho System 50H Cytofluorograf with a 2150 computer).

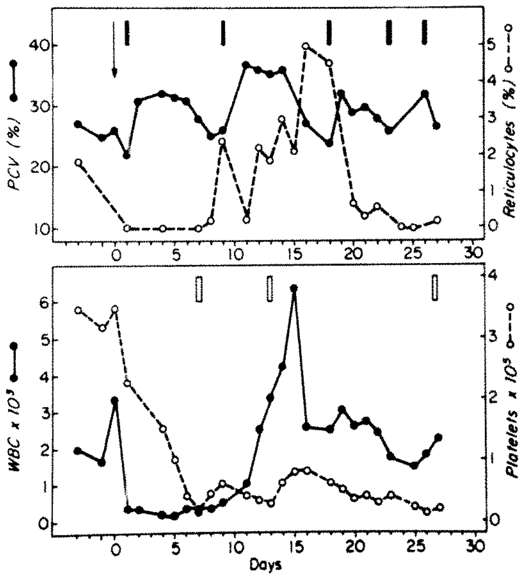

Fig 1. Hematological findings in the recipient. The arrow indicates day of transplantation. Solid bars, red cell transfusions; open bars, platelet transfusions. After the initial hemopoietic recovery with WBC and reticulocyte counts peaking at two weeks, the patient began to deteriorate clinically (fever, sepsis), and his peripheral blood counts started to decline.

Controls for the globin studies were obtained by culture of liver cells from human second trimester abortuses. As a control for posttransplantation globin expression, data from studies of bone marrow transplant recipients (11 aplastic anemia and 4 thalassemia major patients from 15 months to 33 years of age) 3 to 5 weeks posttransplant were used. Control cells for the iI studies were culture-derived erythroblasts from fetal liver BFU-E, from cord blood BFU-E, from blood BFU-E of a patient with homozygous β^+ thalassemia, and from two other patients with thalassemia major studied for 30 and 50 days after their bone marrow transplantation from HLA-identical siblings.

RESULTS

Globin biosynthesis in bone marrow (BM) and peripheral blood (PB) was done two and three weeks posttransplant. Both marrow samples were rich in erythroid precursors, although the marrow on day +21 was somewhat hypocellular. The $\gamma/\gamma + \beta$ ratios were 0.89 and 0.93 for BM and PB, respectively, at day +14; and 0.94 for BM at day +21 and 0.93 for PB at day +22. Circulating red cells from a posttransplant day 21 sample were stained with anti-γ chain monoclonal antibody. Twelve percent of the cells were brightly stained F cells. The discrepancy between number of circulating F cells and globin chain biosynthesis reflects the presence of transfused adult erythrocytes in the patient's blood.

Erythroid cultures were performed with BM and PB drawn on day -21. Bone marrow cloning efficiency at day 8 of culture was 605 colonies per 10^5 cells for the cultures containing FCS and 452 colonies per 10^5 plated cells in cultures containing fetal sheep serum. In contrast to the small-sized (CFU-E-like) colonies present in adult bone marrow cultures at these culture days, large burst-like colonies were present in the cultures of cells from the recipient. Such colony growth is characteristic of fetal liver cultures.[15] The cloning efficiency for BM BFU-E was $243/10^5$ for 11-day BFU-E and 75 and $160/10^5$ for 16-day BFU-E in plates containing FCS and fetal sheep serum, respectively. Circulating BFU-E were 28 and $85/10^5$ in FCS and fetal sheep serum cultures, respectively.

Globin biosynthesis in pooled BFU-E clones was measured in cohorts of erythroid bursts maturing sequentially in culture. All α/non-α chain ratios were balanced. In the bone marrow cultures $\gamma/\gamma + \beta$ ratios ranged from 0.9 to 0.98; in peripheral blood BFU-E cultures, they ranged from 0.87 to 0.96 (Figs 2 and 3). These ratios were in the range of fetal liver BFU-E cultures reported before[15-17] and of two fetal liver control cultures performed during the same time period. There was no increment in β globin biosynthesis when the erythroid bursts of the recipient were grown in fetal sheep plasma (Fig 3).

Globin expression in individual clones was evaluated with two approaches. First, plasma clot cultures were stained with anti-γ and anti-β chain antibodies, and the globin expression in individual bursts was assessed. There was weak labeling with the anti-β chain antibody, but a strong homogeneous labeling with anti-γ chain antibody (Fig 4). More than 100 labeled bursts were evaluated; all displayed the strong anti-γ chain labeling characteristic of the fetal erythroid bursts reported before.[16]

Second, globin chain biosynthesis was measured in individual erythroid clones (Figs 5 and 6). As shown in Fig 6, in all clones analyzed $\gamma/\gamma + \beta$ ratios were >0.85; analyses of single clones from cultures of two fetal liver controls provided similar results (Fig 6).

Figure 7 shows the FACS-derived profile of anti-i and anti-I labeling of erythroblasts from colonies of the recipient and of three controls. Characteristically, the patient's erythroblasts (Fig 7A) showed predominance of i expression over I expression; their FACS profile was typical of that obtained with fetal liver BFU-E-derived erythroblasts (Fig

7B) and distinctively different from the profile of the cord blood BFU-E–derived erythroblasts (Fig 7C) or of erythroblasts from the BFU-E colonies of a patient with homozygous $\beta+$ thalassemia (Fig 7D) and of the two thalassemic patients in the early posttransplantation period (data not shown) which showed a typical adult pattern of iI labeling, similar to that shown in Fig 7D.

DISCUSSION

In this study, transplantation of fetal liver cells to a recipient with ablated erythropoiesis led to early engraftment and establishment of trilineage hemopoiesis, consistent with previous observations in patients transplanted with fetal liver cells.[7-9] Three weeks posttransplantation, detailed studies were done on the erythroid progenitors present in bone marrow and peripheral blood from the recipient as well as on erythroid cells maturing in vivo. The colonies produced in culture had features that were typical of fetal origin erythroid colonies. First, the $\gamma/\gamma+\beta$ biosynthetic ratio was in the range observed for fetal erythroid cells. Second, the pattern of globin chain synthesis was unchanged after the addition of fetal sheep serum, a finding that distinguishes the fetal erythroid colonies from the neonatal and the adult erythroid colonies.[11] Third, the growth characteristics of progenitors (colony number, size, and time of appearance in culture) were reminiscent of fetal liver progenitors. Fourth, the pattern of expression of iI antigenic system in culture-derived erythroblasts was typically fetal.[18] Taken together, these results reveal that a fetal program was encoded by the recipient's erythroid progenitors. That this program was also expressed in the cells maturing in vivo is suggested by the results of globin biosynthesis in peripheral blood reticulocytes and bone marrow cells, which revealed that the in vivo $\gamma/\gamma+\beta$ biosynthetic ratios were in the 0.89 to 0.94 range.

We interpret these observations to suggest that the fetal

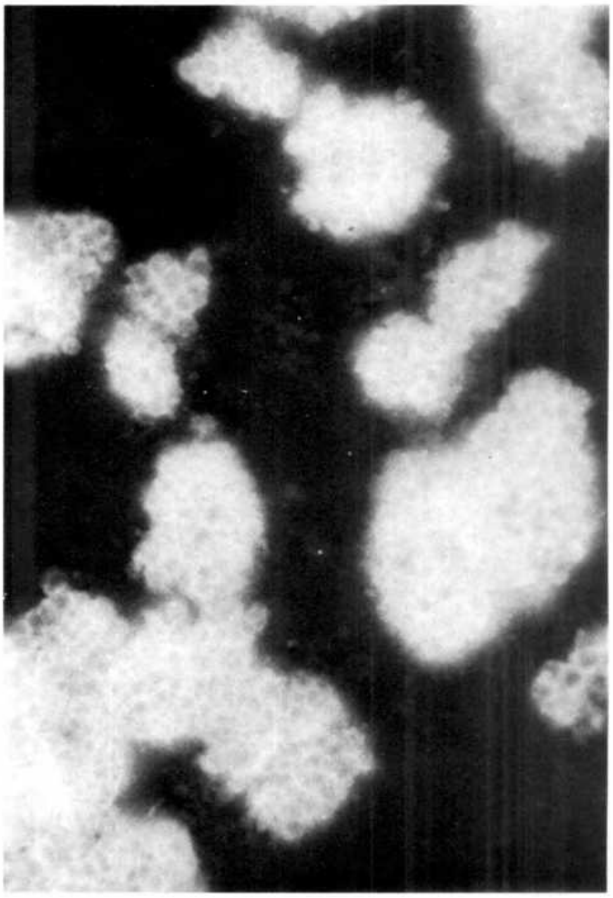

Fig 4. Fluorescent antibody labeling of eight-day erythroid clones from the cultures of the recipient's cells. The preparation was labeled with anti-γ chain monoclonal antibody. Strong homogeneous labeling with the anti-γ chain antibody was the characteristic finding from the analysis of the eight-day clones as well as of all bursts maturing at later culture days.

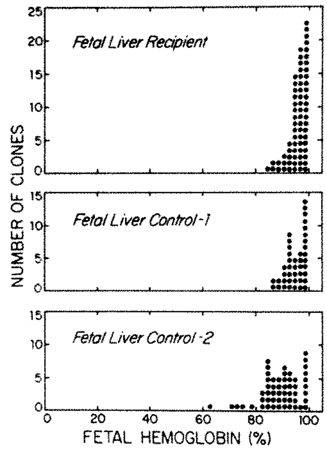

Fig 6. Hb F expression in individual BFU-E clones. Note that all the clones of the recipient show a globin program that is indistinguishable from that of fetal liver-origin control clones.

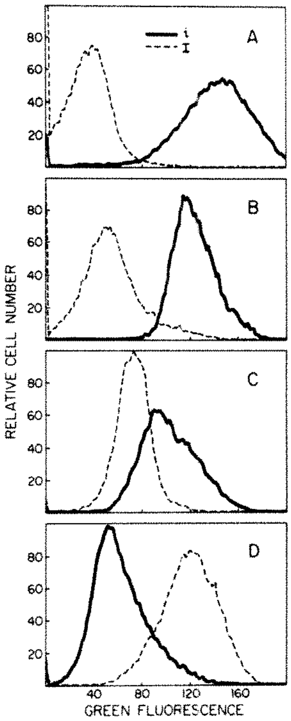

Fig 7. Profiles of anti-I (----) and anti-i (——) labeling. All of the cells are from BFU-E culture-derived erythroblasts. (A) Fetal liver transplant recipient; (B) fetal liver control; (C) neonate; (D) adult with homozygous $\beta +$ thalassemia.

cells that repopulated the recipient's hematopoiesis had failed to switch. It could be argued that our results do not reflect a failure of switching of the donor cells but rather a reactivation of fetal hemoglobin expression post bone marrow transplantation[19,20] or during the acute bone marrow expansion period.[20] Results of globin expression in BFU-E cultures of 15 recipients studied 12 to 33 days posttransplantation (Figs 2 and 3) showed that none of these cases had γ globin synthesis levels approaching the fetal range. In fact, in all cases β globin synthesis in BFU-E–derived erythroblasts exceeded that of γ globin. Furthermore, γ chain synthesis was readily inhibited when the posttransplant cells were grown in fetal sheep serum or plasma (Fig 3), and the pattern of comparative expression profiles of iI antigens in BFU-E–derived erythroblasts from bone marrow cell cultures of two of these recipients resembled that of adult cells. Hence, we think that it is unlikely that a posttransplantation reactivation of Hb F can explain the findings in the fetal liver recipient.

One of the possible mechanisms of control of γ to β switching is environmental induction.[1,3,16,21,22] It can be postulated that an environment, present during the fetal life, instructs the cells to express a fetal program of globin; alternatively, an environment established postnatally could be responsible for the expression by the erythroid cells of the adult globin program. It is also possible that a transient stimulus during the perinatal period could induce switching. The failure of the donor fetal cells to switch following the transplant suggests that the postnatal environment cannot induce switching in cells that have not been intrinsically programmed to switch. This interpretation could be challenged if one argues that switching was not observed in our patient because the environment in children of the recipient's age is not sufficient to induce the adult program in the donor cells. This argument implies that the transplants of young children will result in brisk production of fetal globin in the postengraftment period. Data from 15-month old to 4-year β-thalassemia homozygotes transplanted with bone marrow cells from young siblings have shown that in all instances Hb F levels in BFU-E-derived colonies are within the range observed for adult BFU-E (Fig 3). Furthermore, after transplantation of fetal liver cells in a 7-year-old recipient,[9] synthesis of Hb F in vivo was at levels similar to those we observed in the case reported here.

Although continuation of expression of a fetal program by the transplanted cells diminishes the likelihood that an adult environment alone can induce switching, it does not exclude the possibility that environmental induction plays a role in the control of switching. For instance, it may be argued that a fetal program is induced by the presence of a fetal environment whereas the expression of the adult program occurs in the absence of the fetal environment. Under this hypothesis, the failure of the donor cells to switch could be explained with the assumption that, together with the fetal hemopoietic cells, a cell population that created a "fetal environment" in the recipient's hematopoiesis was co-transplanted. The hypothesis of fetal environment has become less likely from the results of adult to fetus transplantation in the sheep,[2,4] which have shown that adult hemopoietic cells continue to express the adult globin program when they proliferate within a preswitch fetal environment. Additional evidence against this possibility is found in the results of replating of fetal liver origin early BFU-E progeny, which show continuous expression of fetal globin program in secondary plates in the absence of companion cells.[16]

The analyses of single erythroid clones either by immunofluorescence or by globin biosynthesis were done to test whether switching had occurred in a subpopulation of transplanted cells. Our findings suggest that if such a subpopulation existed in the recipient, it was very small in size (<1 in 200 assayable progenitors). The absence of single clones having an adult program is of relevance to the clonal evolution models of switching. Such models have been first proposed to explain switching from embryonic to definitive globin formation in birds and amphibia[24] and subsequently expanded to the explanation of switching in humans.[25–27] In the case of γ to β switch, the simplest assumption is that a fetal stem cell lineage is replaced by an adult stem cell lineage as development proceeds. Lineage models require a number of additional assumptions. For instance: the proliferative behavior of lineages could be controlled intrinsically by programs linking extinction or expansion of a lineage to developmental time, or expansion or "dormancy" of a lineage could be controlled by the prevailing environment. Our results are relevant only to a lineage model that also assumes a selective advantage, of each of the two putative stem cell lines, in either a fetal or in an adult environment. With such a model, the putative "adult" stem cells coexist with the fetal stem cells during the early stages of development, but remain dormant. If that were the case, expansion and differentiation of the adult stem cell lineage and extinction of the fetal lineage would be expected once the cells were placed in a postnatal environment. The absence of adult clones in our recipient argues against this hypothesis. Our results cannot exclude the possibility that an adult lineage exists but had migrated out of the liver of the 18-week fetuses, or that this lineage was present in the transplanted cells but could not proliferate because the developmental signal for its proliferation was not turned on. No permanent grafts have been obtained following transplantation with fetal liver cells; patients either die early or they survive longer with autologous marrow reconstitution (G. Lucarelli, unpublished observations). Thus, one could argue that the early trilineage engraftment in these patients is derived from preprogrammed committed progenitors rather than pluripotent progenitors, the latter being the only ones susceptible to reprogramming by the new environment. This discussion points to some of the inherent difficulties in interpreting the results of the existing in vivo experiments, in view of the multiple hypotheses that can be proposed for the control of switching.

Fetal to adult transplantations in sheep have shown that the developmental time from which the donor fetal cells derive is a variable that determines whether the engrafted cells will or will not switch.[5,6] Thus, cells from early fetuses fail to switch, whereas cells from later fetuses do switch; the rate of switching appears to depend on the developmental age of the fetus.[5,6] Such results support a purely intrinsic mechanism of switching, perhaps controlled by an intrinsic developmental clock,[5,16] or a model assuming that developmental time changes the ability of the cells to interact with environmental stimuli.[11] Our results are compatible with either of the latter two models, since it can be assumed that the donor fetal cells did not switch because their signal of switching or their ability to interact with their environment had not yet been activated.

Progressive Dysfunction of Monocytes Associated With Iron Overload and Age in Patients With Thalassemia Major

By Isidro J. Ballart, María E. Estevez, Luisa Sen, Roberto A. Diez, Julia Giuntoli, Susana A. de Miani, and Jorge Peñalver

We evaluated phagocytic and lytic activities of peripheral blood monocytes (PBMo) from patients with thalassemia major(ThP) using *C pseudotropicalis* as the target. PBMo from ThP showed decreased lytic activity ($P < .001$), whereas the phagocytic activity did not differ from that of the controls. Significant inverse correlations were found between lytic activity of PBMo and age of patients ($r^2 = .47$; $P < .01$) and also between lytic activity and serum ferritin levels ($r^2 = .65$; $P < .001$). No association was found between lytic activity and other variables (blood transfusion regimens, therapy with desferrioxamine, liver damage, and the presence of sHBAg). Splenectomy showed no positive effect on PBMo functions from ThP. Our results suggest that PBMo from ThP have an intracellular defect in their microbicidal mechanisms associated with iron overload. This cell dysfunction could be responsible, at least in part, for the increased susceptibility to infections reported in ThP.

© 1986 by Grune & Stratton, Inc.

PATIENTS WITH homozygous β thalassemia require regular blood transfusions to prevent severe, symptomatic anemia.[1] With time, however, the benefits of this regimen are gradually overshadowed by the effects of the iron overload that is inevitably induced.[2] In these patients iron accumulation in many organs, including the heart, liver, spleen, and endocrine glands, indicates a poor prognosis.[3] Splenectomy performed for the hypersplenism which often occurs in this disease renders these patients more susceptible to infections.[4] Many reports show alterations in both humoral and cellular immunity in this disease, although some of them are discordant.[5-14] Macrophages play a major role in both host defense and iron storage.[15] Although impaired functions of the mononuclear phagocytes should be expected in this disease, very little is known about them.[16,17] In an initial work, we demonstrated that the lytic activity of polymorphonuclear (PMN) leukocytes from thalassemic patients was markedly decreased, whereas their phagocytic function was normal.[5] The purpose of this investigation was to study the phagocytic and microbicidal activities of peripheral blood monocytes (PBMo) from patients with thalassemia major.

We also evaluated the effect of splenectomy on these functions and attempted to determine whether there was any association between phagocytosis and intracellular killing by monocytes and several clinical features of the thalassemic patients, including age, serum ferritin levels, liver damage, and treatment with chelating agents.

MATERIALS AND METHODS

Patients and controls. We studied 22 patients with homozygous β thalassemia, 10 females and 12 males, whose ages ranged from 1 to 24 years. Sixteen of the patients were nonsplenectomized (7 females and 9 males with ages ranging from 1 to 23 years) and 6 were splenectomized (3 females and 3 males with ages ranging from 12 to 24 years). Six of the 16 nonsplenectomized patients underwent splenectomy during the course of this study and were also evaluated after the removal of their spleens. Eight patients were under treatment with iron chelators (deferoxamine, 25 to 45 mg/kg, administered by continuous subcutaneous infusion using a portable pump). Eleven patients were under a "hypertransfusion" program to maintain their hemoglobin levels at >10 g/dL; the other 11 patients were under a "supertransfusion" program, to maintain their hemoglobin levels at >11.5 to 12 g/dL. The diagnosis of thalassemia major was made at the Hospital de Niños de Buenos Aires by standard hematological methods, hemoglobin analysis, and family studies. Adult patients and parents of the children with thalassemia gave their consent prior to entering the study. Blood samples were obtained immediately prior to transfusion of the patients. Our control group consisted of 19 normal subjects (9 females and 10 males with ages ranging from 3 to 46 years). Among them were nine normal children who were studied while undergoing routine blood analysis prior to plastic surgery; parental consent was obtained.

Preparation of yeast cells. We used *C pseudotropicalis*, strain 565, obtained from the Laboratory of Parasitology, Medical College of Paris. The yeast cells were cultured for eight hours at 37 °C on Saboureaud glucose-agar slants and were then collected, washed in Hanks' balanced salt solution (HBSS), and counted. To opsonize the yeast cells, 100 μL of pooled noninactivated normal human AB serum was added per 5×10^6 yeast cells; after several minutes, TC 199 medium (GIBCO, Grand Island, NY) was added to a final concentration of 5×10^6 yeast cells per milliliter.

Isolation of mononuclear cells and study of monocyte functions. Mononuclear cells were isolated from defibrinated peripheral blood by Ficoll-Hypaque density gradients (d = 1.077).[18] Cells at the interphase were collected, washed twice with HBSS, and resuspended in RPMI 1640 medium (GIBCO). Smears were stained with May-Grünwald-Giemsa. The percentage of monocytes after Ficoll-Hypaque separation ranged between 5% and 23%. In a previous study, we evaluated the optimal conditions for adherence of human PBMo.[19] We found that the maximum number of cells adhered to the coverslips when 2.5 to 3×10^6 cells per milliliter in RPMI 1640 with 20% of pooled heat-inactivated normal human AB serum were cultured in Leighton tubes for 18 to 24 hours. Ninety percent to 95% of the adherent cells were monocytes.

After separation with Ficoll-Hypaque, the cells were cultured as above, using the same lot of pooled heat-inactivated normal human AB serum for patients and for normal controls. At the end of the incubation period, supernatants were removed, and glass coverslips were washed twice with warm TC 199 medium. One milliliter of the opsonized yeast cells was added to each Leighton tube. The tubes were incubated at 37 °C and phagocytosis and lysis were allowed to

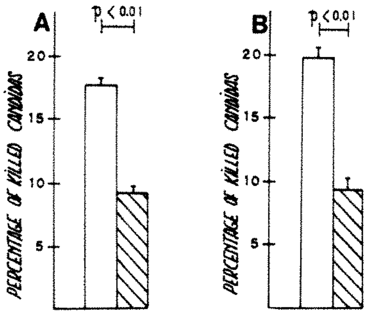

Fig 1. **Monocyte lytic activity from nonsplenectomized thalassemic patients (n = 16) and normal controls (n = 19) after (A) 30 and (B) 60 minutes of incubation with *C pseudotropicalis*. Bars represent $\bar{x}$ ± SEM. □, normal controls; ▨, thalassemic patients.**

proceed for 30 and 60 minutes. The extracellular yeast cells remaining in suspension were removed by gently washing the coverslips three times with warm TC 199 medium. To evaluate *Candida* phagocytosis and killing by adherent cells, coverslip monolayers were examined morphologically with Giemsa staining. Phagocytosis was expressed as the number of *Candida* cells ingested per 100 monocytes, and lytic activity was expressed as the percentage of ghost images (dead yeast cells) per 100 ingested *Candida* cells. The evaluation was done under blind conditions.

Serum ferritin concentration. Serum ferritin levels were determined by a two-site immunoradiometric assay based upon the method of Addison et al[20] as modified by Miles et al,[21] using a commercial kit (RAMCO, Houston, Tex).

Statistics. The student *t* test for independent groups and nonlinear correlation test were performed.

RESULTS

Phagocytic and lytic activities of monocytes from nonsplenectomized patients with thalassemia major. We studied the ability of PBMo from thalassemic patients to kill *C pseudotropicalis* after 30 and 60 minutes of incubation with the yeast. The percentages of intracellular killing were ($\bar{x}$ ± SEM) 8.08% ± 0.56% after 30 minutes and 9.5% ± 0.6% after 60 minutes as compared with 18.2% ± 0.3% and 20.0% ± 1.5% in normal controls (Fig 1A and B). The lytic activity of the monocytes from thalassemic patients was statistically decreased as compared with normal controls at both incubation periods ($P < .001$).

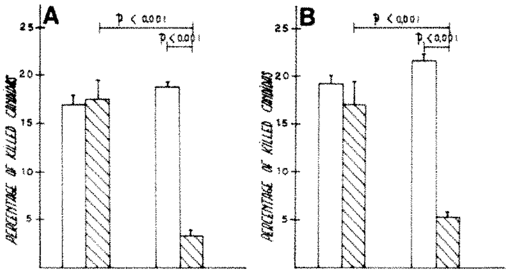

Fig 2. **Comparison of the lytic activities between thalassemic patients and normal controls <10 years or ≥10 years of age after (A) 30 and (B) 60 minutes of incubation with *C pseudotropicalis*. Bars represent $\bar{x}$ ± SEM. □, normal controls; ▨, thalassemic patients.**

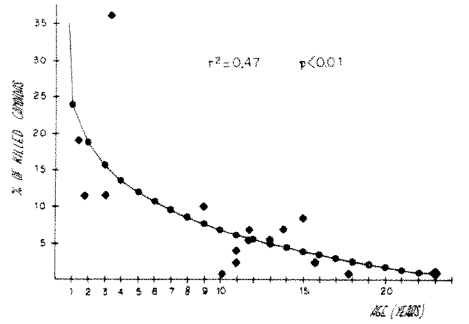

Fig 3. **Correlation between monocyte lytic activity and ages of 16 thalassemic patients studied before splenectomy.**

In order to assess whether there was any relationship between the impairment in the lytic function and the ages of patients, we divided the patients and controls into two age groups: <10 years old and ≥10 years old. As shown in Fig 2A and B, the percentages of killed *candida* cells were ($\bar{x}$ ± SEM): thalassemic patients aged <10 years: 17.7% ± 4.8% and 17.3% ± 5.4% at 30 and 60 minutes, respectively; patients aged ≥10 years: 3.7% ± 0.8% and 5.6% ± 1.2%; normal controls aged <10 years: 17.3% ± 2.3% and 19.3% ± 2.9%; and controls aged ≥10 years: 19.0% ± 1.6% and 21.4% ± 1.8% at 30 and 60 minutes, respectively. According to these results, the ability to kill yeast cells in thalassemic patients aged <10 years was similar to that observed in the age-matched control group, whereas in patients ≥10 years, the lytic activity was significantly decreased as compared with that of age-matched controls ($P < .001$). The statistical analysis of the association between the lytic function of the monocytes and the age of the patients showed an inverse correlation between both variables ($P < .01$) (Fig 3).

To assess whether the age-related defect in the lytic activity of the monocytes was associated with iron overload, we determined the serum ferritin concentration in 13 patients. As shown in Fig 4, an inverse correlation between lysis and serum ferritin levels was found ($P < .001$).

We also determined whether any association existed between monocyte lytic activity and therapy with chelating agents. No differences were found between thalassemic patients who were under treatment with deferoxamine for at least one year and those who were untreated (data not

shown). Neither were any differences found between patients receiving supertransfusions and those receiving hypertransfusions; no association was found with other clinical parameters, including liver damage (as measured by liver size and serum glutamic pyruvate transaminase), serum proteins, or the presence or absence of surface hepatitis B antigen (sHBAg) (data not shown).

Table 1 shows phagocytosis by PBMo from thalassemic patients as compared with those of normal controls. No statistically significant differences were found between them after 30 or 60 minutes. Neither were differences found between patients younger or older than 10 years of age.

Effects of splenectomy on the monocyte functions. To evaluate the effect of splenectomy on the phagocytic and lytic activities of the monocytes from patients with thalassemia, we studied 13 splenectomized thalassemic subjects, six of whom had been previously studied before undergoing splenectomy. No differences were found in phagocytic or lytic functions between the splenectomized and nonsplenectomized patients (Table 2). The six patients studied before and after splenectomy showed no differences in phagocytosis; the already impaired lytic activity decreased even more after the removal of the spleen, being statistically significant at 30 and 60 minutes ($P < .05$) (Table 3).

DISCUSSION

Our study demonstrates that PBMo from nonsplenectomized patients with homozygous β thalassemia have an age-related defect in their microbicidal activity against *C pseudotropicalis* with a preserved phagocytic function. The deficiency in the intracellular killing of *Candida* cells is associated with iron overload and is not corrected by splenectomy.

There is evidence that patients with Cooley's anemia are particularly prone to infections, particularly after splenectomy.[4,22-24] In these patients, *S pneumoniae* is a major pathogen. Elimination of *S pneumoniae* from the bloodstream depends upon a correct humoral response and the integrity of the reticuloendothelial system.[25] Several authors have reported abnormalities in both humoral and cellular immunity in thalassemia major, but some of these results are discordant.[5-14] The few reports on the mononuclear phagocyte system in thalassemia evaluated the reticuloendothelial phagocytic capacity by the clearance of radiolabeled materials[16,17] and found a borderline low value. To assess the monocyte functions, we selected *C pseudotropicalis* as a target microorganism because these yeast cells are killed mainly through oxygen-dependent, myeloperoxidase-independent lytic mechanisms,[26] which are the main microbicidal systems that operate in mononuclear phagocytes.[27]

The alteration found in the lytic system of PBMo from thalassemic patients is coincident with that previously reported in PMN cells.[5] The candidacidal activity against *C pseudotropicalis* directly correlates with the chemiluminescence response evoked by stimulation with opsonized zymosan in PMN and monocytes (I. J. Ballart et al, manuscript in preparation). Preliminary data in monocytes from two thalassemic patients showed that both had a decreased candidacidal activity (<2%) and a very low monocyte chemiluminescence in response to opsonized zymosan stimulation. The defect found in the myeloperoxidase-independent microbicidal mechanisms could be caused by iron overload. It is known that patients with thalassemia major develop iron overload as a consequence of regular blood transfusions and ineffective erythropoiesis.[2] Iron storage increases with the age of the patients. Serum ferritin levels provide a useful estimation of iron storage.[28] It has been shown that iron interferes with bactericidal activity (by reducing H_2O_2) and phagocytosis (by the spontaneous generation of free radicals which damage the cells).[29,30] We found that serum ferritin levels were inversely correlated with the microbicidal activity of the monocytes and that the lytic activity decreased as the patients grew older. These findings suggest an association between iron overload and the impairment in the lytic activity of monocytes. Iron overload may also affect phagocytosis, ie, in idiopathic hemochromatosis.[31] Although the phagocytic activity of PBMo from patients with thalassemia tended to be lower than that of normal controls, no statistical significance was found. However, we cannot dismiss the possibility that the apparent differences found in killing reflect, at least in part, differences in complete ingestion.

	Phagocytosis*		Lytic Activity†	
	(30 min)	(60 min)	(30 min)	(60 min)
Before splenectomy	417 ± 24	441 ± 30	3.1 ± 1.0	4.4 ± 1.7
After splenectomy	403 ± 29	418 ± 47	0.7 ± 0.2	1 ± 0.3

*Number of ingested *Candida* cells per 100 adherent cells ($\bar{x}$ ± SEM).

†Percentage of killed *Candida* cells within the adherent cells ($\bar{x}$ ± SEM).

The treatment with chelating agents in patients with thalassemia did not modify the lytic function or serum ferritin levels; neither was any association found between cell dysfunction and blood transfusion programs, liver damage, serum protein concentration, and the presence of sHBAg. Splenectomy did not improve the monocyte function. On the contrary, the already impaired lytic activity became worse after removal of the spleen.

In conclusion, monocytes from patients with thalassemia major have an intracellular defect in their microbicidal mechanisms, associated with iron overload. Neither splenectomy nor chelating agent therapy could revert this impairment. This cell dysfunction could be responsible, at least in part, for the increased susceptibility to infections reported in thalassemia major.

Influence of Oxygen Tension on the Viscoelastic Behavior of Red Blood Cells in Sickle Cell Disease

By Gerard B. Nash, Cage S. Johnson, and Herbert J. Meiselman

Although the rheological behavior of sickle cell suspensions and of hemoglobin S solutions is known to be strongly dependent on oxygen tension (Po_2), little data exist concerning the influence of Po_2 on the viscoelasticity of 2ndividual HbSS RBC. We have used micropipette aspiration techniques to test the deformation response of both HbSS and control HbAA RBC over a wide range of Po_2 at 23 °C. Sickled, spiculed HbSS cells were present for $Po_2 \leq$ 35 mm Hg; for a number of these cells, the deformation response was essentially elastic and an effective membrane rigidity (EMR) was calculated. EMR increased with decreasing Po_2 and was ~5 to 50 times higher than the equivalent rigidity of oxygenated HbSS RBC. In addition, the rate of membrane deformation was very slow for sickled cells; the half-time for the deformation process increased as Po_2 was lowered and was about two orders of magnitude longer than the equivalent time for normal RBC. Other sickled cells exhibited plastic deformation when subjected to comparable deforming forces and experienced irreversible membrane deformation and budding. At all Po_2 levels tested, some HbSS RBC remained as discocytes; these cells had normal membrane elasticity and membrane viscosity. Furthermore, changes in Po_2 did not affect the membrane properties of HbAA RBC. Thus, gross abnormalities in the deformation response of HbSS RBC were only detected after morphological sickling had occurred. These abnormalities most likely arose from changes in the cytoplasmic HbS viscoelasticity and, if present in vivo, would be expected to impair the flow of HbSS cells in the microcirculation.

© 1986 by Grune & Stratton, Inc.

THE ABILITY to undergo repeated deformation is a necessary requirement for RBC to pass through the microcirculation, and it is generally agreed that impairment of this ability results in blood flow disturbances. In sickle cell (HbSS) disease, the RBC have abnormal mechanical characteristics, and these abnormalities have been implicated in the pathological process.[1] This role of the RBC in the pathogenesis of HbSS disease has led many workers to study the rheological properties of both sickle cells and hemoglobin S (HbS) solutions. It has been demonstrated that, even when fully oxygenated, RBC suspensions and individual HbSS RBC exhibit abnormal rheological behavior: (1) sickle cell suspensions have impaired filterability[2,3] and elevated viscosity[4] as compared with normal RBC suspensions at equal hematocrit; (2) for dense HbSS RBC, cellular abnormalities include a more rigid cell membrane, an elevated internal viscosity, and a decreased overall cellular deformability.[5-9] These changes become accentuated when oxygen tension (ie, Po_2, partial pressure of oxygen) is lowered. At $Po_2 < 20$ mm Hg, sickled RSC (reversible sickle cells) have greatly reduced membrane and cellular deformability[10]. In addition, as Po_2 falls, the viscosity of HbSS RBC suspensions progressively increases and their filterability becomes further impaired[3,11,12]; these changes begin at Po_2 levels above those necessary to cause RBC sickling (ie, morphological transformation of cells to characteristic "holly leaf" or elongated forms with spicules). However, a small fraction of the intracellular HbS may be polymerized at these Po_2 levels; this polymer fraction appears to be insufficient to cause morphological changes but great enough to initiate flow disturbances.[13]

It appears most likely that the Po_2-dependent changes in sickle cell properties noted above arise from alterations in the physical state of the cytoplasmic HbS. This interrelation of cellular rheological behavior and cytoplasmic properties has been demonstrated by Chien et al[14] in studies of the viscoelastic behavior of sickle cell suspensions and of HbS solutions. Although suspensions of both oxygenated HbSS and normal RBC exhibit viscoelastic behavior (ie, have measurable viscous and elastic components of the complex viscosity), only sickle cell suspensions show increasing viscoelastic components with decreasing oxygen tension.[14] These changes in suspension viscoelasticity can be correlated with alterations in the cytoplasm of the HbSS RBC, in that cell-free HbS solutions have no elastic component when oxygenated but develop viscoelastic characteristics with decreasing Po_2. In fact, the viscous and elastic components become so great for HbS solutions that Chien et al[14] have suggested that the viscoelastic behavior of HbSS RBC suspensions at low oxygen saturations is dominated by the RBC cytoplasmic properties. The potential influence of cytoplasmic alterations on cellular behavior is also demonstrated by the finding that, at zero Po_2, HbS solutions form gels, exhibit "solid-like behavior," and have a threshold stress level (ie, a yield stress) for the initiation of flow.[15]

In contrast to studies of RBC suspensions and of HbS solutions, few data exist for the effects of Po_2 on the mechanical properties of individual HbSS RBC. Both the resistance to deforming forces and the rate of the deformation response are likely to change for HbSS RBC as Po_2 is decreased, and both these characteristics will influence RBC flow behavior in vivo. Although it is known that sickled cells are more resistant to deformation at reduced Po_2,[10] little is known of the dynamic aspects of their response. Nor is it known at what Po_2 these viscoelastic characteristics first become altered, how the alterations vary with Po_2, or

whether alterations occur for cells that have not undergone morphological sickling. The present investigation was designed to explore these questions by carrying out micropipette aspiration studies of individual HbSS RBC over a wide range of oxygen tensions. For sickled HbSS cells, membrane tongues were aspirated into pipettes with diameters in the range of 1.2 to 1.6 μm; the rate and final extent of membrane deformation were measured. In a similar manner, the membrane shear elastic modulus (μ) (ie, membrane rigidity) was measured for normal HbAA cells and for HbSS RBC which remained in the normal discocytic shape. Discocytes were also subjected to extensional recovery measurements where, after micropipette elongation, the rates at which they regained their resting shapes were determined. Our aim was to interrelate changes in cytoplasmic state with alterations in cellular viscoelasticity and morphology, and to gain a better understanding of the role that RBC mechanical abnormalities may play in the pathogenesis of sickle cell disease.

MATERIALS AND METHODS

Donor population and RBC suspensions. Blood samples were obtained from a total of 21 patients with homozygous HbSS disease, with the approval of the University of Southern California Human Subjects Research Committee. Patients were defined by the usual hematologic criteria.[16] Excluded from the study were patients in sickle cell crisis and those who had received transfusions within the prior three months. All patients were seen at the Comprehensive Sickle Cell Center, Los Angeles County–University of Southern California Medical Center, Los Angeles. Control samples were obtained from healthy adult laboratory personnel. Blood was collected by venipuncture into heparin (5 IU/mL) and measurements were completed within 24 hours of withdrawal. All cell preparations and measurements were carried out at room temperature (23 ± 1 °C) unless otherwise specified.

Two different buffered saline solutions were used: phosphate-buffered saline (PBS, 0.122 mol/L of NaCl, 0.03 mol/L of KH_2PO_4 + Na_2HPO_4, 0.2g/dL of glucose, pH 7.4, 300 mosmole/kg) and bicarbonate-buffered Ringer solution (BRS, 0.128 mol/L of NaCl, 0.025 mol/L of $NaHCO_3$, 0.003 mol/L of KCl, 0.002 mol/L of $MgSO_4$, 0.0025 mol/L of $CaCl_2$, 0.1g/dL of glucose, equilibrated with 95% air/5% CO_2, pH 7.4, 300 mosmole/kg). To these buffers was added either 0.2g/dL of human serum albumin (HSA) or 9% vol/vol autologous plasma. Except where stated otherwise, RBC suspensions were made by diluting whole blood to a hematocrit of ~0.05% in these media.

Micropipette apparatus. The microscope-video and micropipette systems were as previously described.[8,17] The micropipette chambers used for the cell suspensions were modified to minimize air/sample contact and thus to decrease the rate at which Po_2 would rise for the suspensions with low oxygen tension. The chambers were fabricated from standard glass microscope slides and coverslips, separated by rectangular, 1-mm thick parafilm gaskets. The gaskets had narrow openings (5-mm) on one edge for pipette entry and the final size of the chambers was 27 × 15 mm. Micropipette manipulations of the RBC were carried out in the central part of the chamber, ~10 to 12 mm from the entrance. The pipettes were hydraulically coupled to a micrometer-driven hydrostatic reservoir for variation of the aspiration pressure (P). Because for some measurements relatively high P and rapid changes in P were desired, this system could be switched, by a valve, to a closed, fluid-filled system. The pressure in this closed system was varied using a screw-driven, gas-tight syringe (Hamilton Co, Reno, Nev), and was measured using a Validyne pressure transducer (model DP7, Validyne Engineering Corp, Northridge, Calif). The two pressure systems could be interconnected for zero pressure adjustment and for calibration purposes.

Variation of Po_2 and measurement of RBC viscoelasticity. Two types of studies were carried out at various Po_2 levels: (1) measurement of sickled, spiculed HbSS cells by observation of their time-dependent response to changes in micropipette aspiraton pressure; and (2) measurement of disc-shaped HbSS and control HbAA cells by micropipette determination of the membrane μ and the time constant (tc) for shape recovery. Different preparative and measurement procedures were used for these experiments.

Sickled HbSS RBC. HbSS RBC, suspended in 15 mL of BRS plus plasma, were placed in a 125-mL flask and orbitally shaken while a humidified 95% N_2/5% CO_2 gas mixture was blown over the liquid surface. After an interval (usually 5 to 30 minutes, depending on the Po_2 desired), a portion of the suspension was withdrawn into a syringe through narrow-bore plastic tubing. The Po_2 of the suspension in the syringe was measured, and a portion of the suspension from the same syringe was then introduced into the micropipette chamber, which had been previously flushed with humidified 95% N_2/5% CO_2. Following micropipette analysis (ie, after ~20 to 45 minutes), the suspension in the chamber was withdrawn, and its Po_2 was remeasured.

The viscoelastic behavior of sickled cells was tested by measuring the time-dependent response of membrane tongues which were aspirated into micropipettes with an internal radius (Rp) in the range of ~0.6 to 0.8 μm. A small initial suction pressure (eg, 3 mm H_2O) was applied to the micropipette, and its tip was placed in contact with a smooth region of the surface of a sickled cell, away from spicules or sharp edges (see Fig 1). This small initial pressure did not cause deformation of the sickled cells and served only to hold the cell to the pipette tip. The P was then rapidly increased (ie, in ~1 to 2 seconds) using the closed pressure system, and the membrane tongue growth was observed and video recorded. Depending on the Po_2 of the suspension, the pressures applied ranged up to 500 mm H_2O. After a period of time (usually ≳ 1 minute), P was either further increased or was reduced in steps. From the video recordings, tongue length was measured as a function of time during both the pressure increase (ie, loading) and decrease (ie, unloading) portions of the experiment.

Discocytic HbSS and HbAA RBC. During the above mentioned studies of sickled cells, it was noted that some HbSS RBC remained

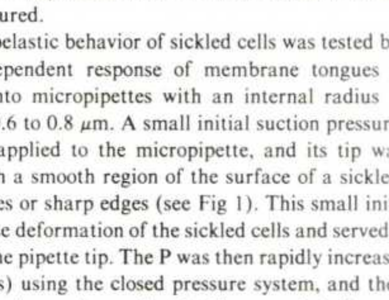

Fig 1. Photograph taken from a video recording of micropipette aspiration of a spiculed, sickled HbSS RBC. The Po_2 was in the range of 30 to 50 mm Hg, the pipette radius was 0.6 μm and the aspiration pressure was 30 mm H_2O; the resultant tongue length was approximately equal to two pipette radii (ie, L/Rp ~ 2). Note that the portion of the cell outside of the pipette was not distorted by the aspiration process.

in the normal, discocytic shape at all Po_2 tested. To study the mechanical properties of these discocytic HbSS cells, as well as of those of HbAA erythrocytes, a different preparative procedure was required. It was necessary to use cells which were point-attached to the upper surface of the micropipette chamber and to use buffer/HSA and buffer/plasma mixtures that had various fixed and predetermined Po_2 levels. In addition, it was necessary to manipulate these buffers and the micropipette chamber in an environment with a defined Po_2. To meet these requirements, gas mixtures containing desired proportions of N_2 and air were prepared using a dual flow-meter (Air Products Inc, Tamaqua, Pa), and all sample preparation and chamber loading procedures were carried out inside a glove box that was continuously purged with the gas mixture. Cells suspended in PBS plus HSA, and cell-free PBS plus plasma were equilibrated for 30 minutes with a gas mixture; a portion of the cell suspension was then loaded into a gas-flushed micropipette chamber. The chamber was then inverted for 10 to 20 minutes to allow cells to settle and attach to its upper surface. The PBS plus HSA was subsequently aspirated from the chamber and replaced with PBS plus plasma at the same Po_2; the presence of plasma in the medium inhibits further cell adhesion to glass surfaces during measurements of tc.[18] In this series of experiments, Po_2 was measured for the original cell suspension, for the original PBS plus plasma mixture and, after micropipette analysis, for the contents of the micropipette chamber.

Discocyte viscoelastic behavior was quantitated by measuring the tc for extensional shape recovery and the membrane μ. The membrane surface shear viscosity was calculated from these measured parameters by the relation, $\eta_m = \mu \cdot tc$.[18] The methods for measuring tc and μ were those previously described by Nash et al.[8] To determine tc, the length and width of a point-attached cell were measured at intervals after it had been elongated by micropipette manipulation and then released. The exponential shape recovery process was analyzed, and tc was calculated by the method of Hochmuth et al.[18] The membrane μ was measured by the micropipette method of Evans and LaCelle[19] for cells detached from the chamber surface. A membrane tongue was aspirated from the cell's flat surface into a micropipette of radius Rp (Rp = 0.6 to 0.8 μm) and the tongue length (L) was measured as the P was raised in steps. The rate of change of L with P was determined by linear regression and used to calculate μ, ie, $dL/dP = Rp^2/(2.5\mu)$; this is a linear approximation[20] to the exact theory of Evans.[21,22]

Miscellaneous techniques. The partial pressure of oxygen (Po_2) was measured using a Radiometer Model PH71 system equipped with an oxygen electrode (Radiometer Company, Copenhagen, Denmark). pH was measured by the same Radiometer system, and solution osmolalities were determined by freezing point depression (Model 2007, Precision Systems, Inc, Sudbury, Mass). The percentage of sickled cells present at various Po_2 levels was determined from microscopic observations of fixed cells. For these measurements, RBC suspensions of 1% to 2% hematocrit were either gassed for different time periods with 95% N_2/5% CO_2 or equilibrated with different N_2/air mixtures as described above. The fixative (2% glutaraldehyde in PBS) was gassed or equilibrated in the same manner and mixed at a ratio of 1:1 with the cell suspension. The Po_2 levels of both the original cell suspension and the cell/fixative mixture were measured, and the average was taken. For two donors, the percentage of cells sickled was determined at 37 °C as well as at 23 °C; these suspensions were equilibrated for 30 minutes with N_2/air mixtures of known Po_2. The Po_2 levels of the 37 °C suspensions were not measured, but were assumed to equal those measured for the room temperature suspensions which were concurrently and identically gassed. Sickled cells were categorized as those cells that had altered, angular morphology, usually with long spicules and often with an elongated shape. ISC were included in the total RBC count, but were not considered as sickled unless spiculated.

RESULTS

Data for the percentage of cells sickled *v* Po_2 are shown in Fig 2. At room temperature (23 °C), a lower Po_2 was required to initiate sickling than at 37 °C; for a Po_2 of 17 mm Hg, 50% of cells were sickled at 23 °C, whereas at 37 °C, 50% sickling occurred at a Po_2 of about 35 mm Hg. Unfixed cell preparations, observed in the micropipette chambers, also contained sickled cells if the sample initially had a Po_2 of $\leq$ 35 mm Hg. In these low Po_2 preparations, most ISC retained their oxygenated shape and had no spicules. However, under high magnification ($\times$10,000), video-microscopic observation, it was evident that at low Po_2 these nonspiculated ISC had developed roughened surfaces and a granular or stippled cytoplasm. Moreover, in these preparations, some approximately disc-shaped HbSS cells had a similar surface and cytoplasmic granularity. These nonspiculated ISC and granular disc-shaped cells had morphologies resembling those obtained when dense HbSS RBC fractions are deoxygenated[23] and were easly distinguishable from unaltered, smooth surfaced ISC and discocytes.

Sickled cells exhibited one of two distinct types of deformation response when subjected to micropipette aspiration of membrane tongues, ie, either an essentially elastic or a plastic response (Fig 3). For cells behaving elastically, application of P caused the growth of a tongue whose L increased slowly toward a final stable level. Subsequently, if P was raised further, a new stable length (Lf) tended to be achieved (Fig 3A, cell I). For these cells, if the P was returned to zero, the tongue relaxed without evident residual deformation; P could also be decreased in steps with a concurrent step-wise reduction in L (Fig 3A, cell II). Other cells, with an essentially plastic response, exhibited continuous membrane tongue growth, until a bud of membrane-bound material formed and broke away from the cell (ie, irreversible plastic membrane deformation, Fig 3B, cell I). In some cases,

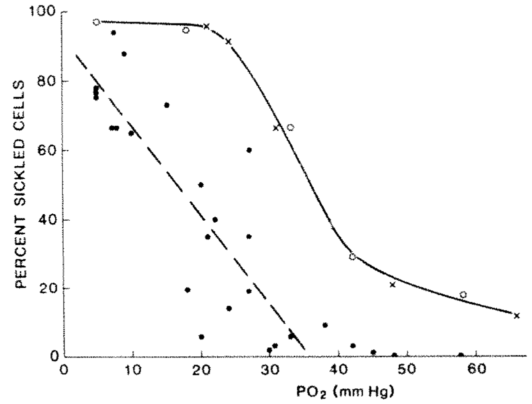

Fig 2. Percentage of sickled cells *v* Po_2 (mm Hg) for samples either at 23 °C ± 1 °C (- - - -) or 37 °C ± 0.5 °C (——). At 23 °C, samples from 12 donors were tested; the line shown was fitted by linear regression of the data for Po ≤40 mm Hg ($r = -.852$, $P < .001$). Two of the 12 samples were also tested at 37 °C (ie, symbols o and x), and the line shown was drawn by hand.

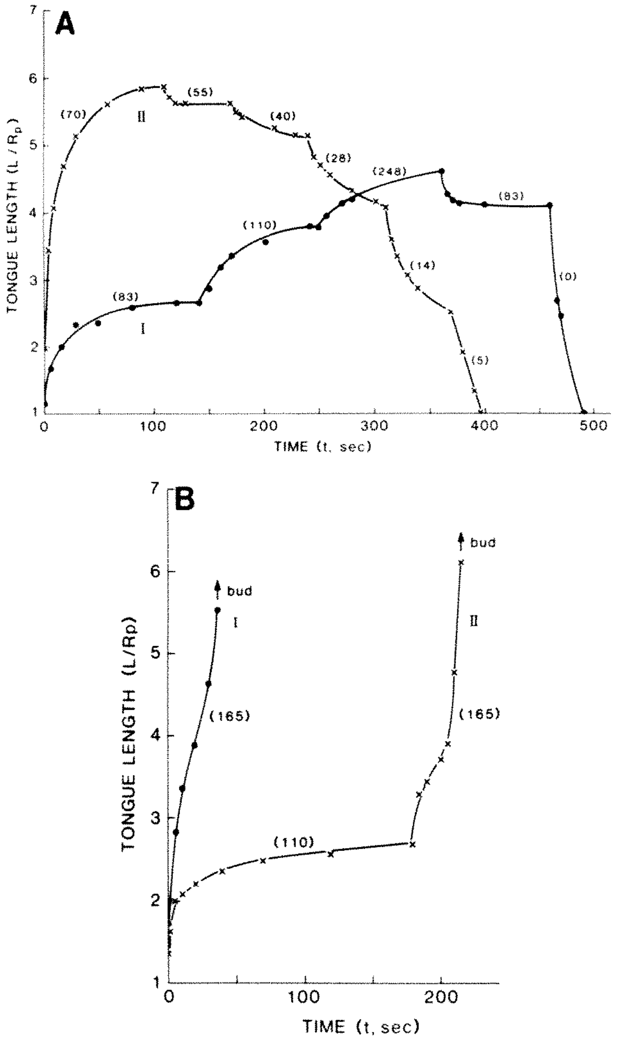

Fig 3. Aspirated membrane tongue length *v* time (seconds) for sickled cells; tongue length (L) is normalized by the pipette radius (Rp). The aspiration pressure (P, mm H_2O) is shown in brackets for each section of the curves. (A) Data for two cells behaving essentially elastically; for both cells Rp = 0.6 μm and Po_2 was in the range of 30 to 50 mm Hg. (B) Data for two cells exhibiting plastic deformation, with membrane buds formed for $L/Rp \gtrsim 6$. For cell I, Rp = 0.8 μm and Po_2 was in the range of 5 to 26 mm Hg; for cell II, Rp = 0.6 μm and Po_2 was in the range of 5 to 40 mm Hg.

residual deformation was seen if P was returned to zero before budding occurred, ie, some membrane remained protruding from the side of the cell. Such residual tongues were crumpled and flaccid, showing that the Hb originally inside the tongue had flowed back into the cell. For some cells, after stable deformation had occurred at one pressure, a subsequent increase in P led to rapid tongue growth and budding (Fig 3B, cell II). Plastic deformation was not analyzed in detail, other than to note that for this type of deformation, budding generally occurred for $L/Rp \gtrsim 6$, and that tongue growth was, on the average, initially several times faster than that of cells which responded elastically. Whenever possible, plastic deformation of cells was avoided; this was achieved by using pressures which were below those necessary to cause irreversible deformation. During either elastic or plastic deformation, the overall sickled cell shape was not perceptibly altered by the micropipette procedure.

Cells that behaved essentially elastically took ~30 to 120 seconds to form a membrane tongue with a stable length Lf. A measure of the rigidity of these cells was obtained by measuring this final Lf for each cell at 1 to 4 increasing pressures. Then an "effective membrane rigidity" (EMR) was calculated in a manner analogous to that used to determine the μ of discocytes. The quotient Lf/P was taken, or if more than one data pair existed, dLf/dP was calculated by linear regression. This value was multiplied by $(2.5/Rp^2)$ and the reciprocal of the product was taken as the EMR. This measure of rigidity (ie, EMR) has the same units as the membrane μ, but we do not imply that it reflects a true membrane property. Rather, EMR values were used to characterize the resistance to deformation of sickled cells at various Po_2 levels and to compare the deformation response of sickled cells and discocytes. Figure 4 shows EMR plotted *v* Po_2; the data demonstrate that the rigidity of sickled cells increases rapidly as Po_2 decreases. If EMR values are compared to the μ values previously obtained for oxygenated HbSS discocytes (mean = 6.7×10^{-3} dyne/cm, see ref 8), it is evident that all sickled cells are highly resistant to deformation. For example, at $Po_2 \sim 35$ mm Hg, the EMR of sickled cells was ~tenfold greater than the μ for discocytes; at $Po_2 \sim 10$ mm Hg, it was ~fifty-fold greater. If the line drawn in Fig 4 is extrapolated to predict the Po_2 at which the

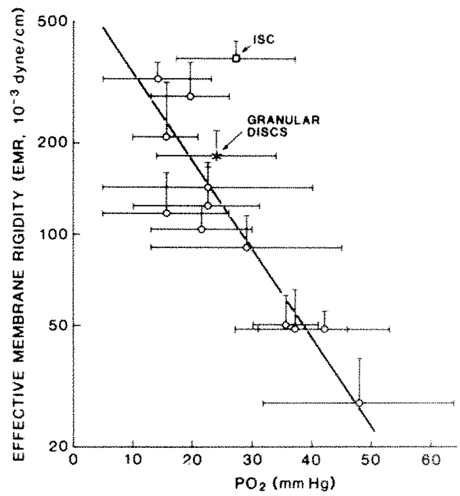

Fig 4. Effective membrane rigidity (EMR, 10^{-3} dynes/cm) *v* Po_2 (mm Hg) for sickled cells behaving essentially elastically. The horizontal bars indicate the range of Po_2 from that measured when the sample was loaded into the chamber to the higher value remeasured after micropipette analysis; all data points are located at the average of these two Po_2 measurements. For spiculed, sickled cells (O), the points represent the mean ± SEM of EMR values from 3 to 7 cells; ten donors were tested at one or two Po_2 ranges. The line drawn represents the linear regression of ln(EMR) against Po_2 ($r = -.955$, $P < .001$). For the nonspiculated, irregular ISC (☐) and the granular discs (•), the data were pooled from three donors tested at similar Po_2 ranges; a total of five ISC and eight discs were tested, and points represent the mean ± SEM.

EMR for sickled cells will equal the above mentioned rigidity (ie, μ) for oxygenated HbSS discocytes, a value of 70 mm Hg is found. However, since at 23 °C sickled cells do not exist above a Po_2 of ~40 to 50 mm Hg (see Fig 2), it seems likely that a step increase in rigidity occurs at the same time as morphological sickling. EMR values for ISC and for discocytes, both with irregular, granulated surfaces, are also shown in Fig 4. These cells had similar or slightly greater rigidity than the spiculed, sickled cells at comparable Po_2 levels.

For sickled cells that behaved elastically, data for tongue L *v* time (eg, Fig 3) were used to carry out an analysis of the rate of the deformation response. When P was first applied, an initial, short membrane tongue (~1 μm) was evident within a few seconds (ie, only slightly longer than the time required to raise P). L then slowly increased towards its final value (Lf). The initial, ~1 μm of tongue growth was not resolvable due to optical limitations, although the time course of the later growth could be analyzed. These length *v* time data did not follow a simple exponential approach toward Lf, and thus a single exponential tc could not be fitted to the data. Instead, half-times ($t^1\!/\!_2$) were used to characterize the rates at which sickled cells responded to deforming forces. This $t^1\!/\!_2$ was taken as the time required for L to increase from its initial value, when a tongue was first optically measurable (Li), to a value of (Li + Lf)/2, ie, halfway to its final length Lf. Figure 5 shows $t^1\!/\!_2$ values plotted as a function of Po_2; the values are based on membrane tongue growth resulting from the first applied pressure step. Half-times varied between ~5 to 35 seconds and were longer for lower Po_2. There was no significant correlation of $t^1\!/\!_2$ with P for a given sample, although it was observed that a longer half-time was usually obtained for the second pressure step. Note that the half-times shown in Fig 5 are approximately two orders of magnitude longer than either the time required for establishment of membrane tongues when normal RBC are aspirated into micropipettes[24] or the time required for recovery of cell shape after micropipette elongation of RSC.[8]

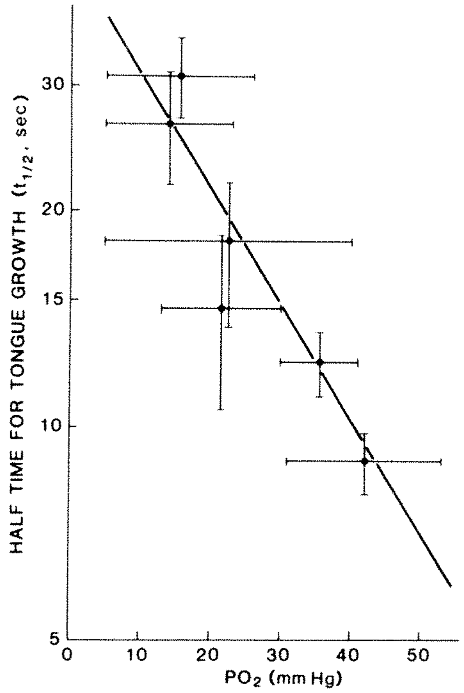

Fig 5. Half-time for membrane tongue growth ($t^1\!/\!_2$, seconds) *v* Po_2 (mm Hg) for sickled cells behaving essentially elastically. The horizontal bars indicate the range of Po_2 from that measured when the sample was loaded into the chamber to the higher value remeasured after micropipette analysis; all data points are located at the average of these two Po_2 measurements. Points represent the mean ± SEM for 3 to 5 cells from each of six donors. The line drawn represents the linear regression of ln ($t^1\!/\!_2$) against Po_2 ($r = -.932$, $P < .01$).

The horizontal bars shown in Figs 4 and 5 represent the increase in Po_2 that occurred between the initial loading of the sample into the micropipette chamber and the final remeasurement of its oxygen tension. However, it is likely that the cells which were actually measured experienced less variation in Po_2 than is indicated by these horizontal bars. When the sample was removed for final Po_2 measurement, fluid from the chamber entry region mixed with fluid from further within the chamber, where the pipette measurements were carried out. We expect the Po_2 to be higher for the outer than for the inner fluid, and thus the final measured Po_2 to be higher than the level experienced by any measured cell. If the horizontal bars in Figs 4 and 5 are indeed overestimates, the true EMR *v* Po_2 and $t^1\!/\!_2$ *v* Po_2 curves may lie slightly to the left (ie, lower Po_2) of the lines drawn, since the points shown are placed at the averages of the measured initial and final Po_2 levels.

Two other abnormalities were noted in the deformation response of sickled cells; both are illustrated in Fig 6, which shows typical data for stable tongue Lf *v* P. First, there was a large degree of hysteresis in the pressure-deformation response when P was reduced; ie, in Fig 6, the Lf *v* P data do not follow the same path for increasing and decreasing P.

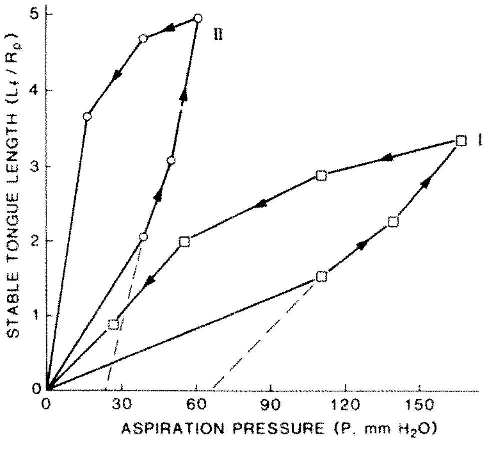

Fig 6. Stable membrane tongue length (Lf/Rp) *v* aspiration pressure (P, mm H_2O), for two sickled cells behaving essentially elastically. For cell I, Rp = 0.8 μm and Po_2 was in the range of 5 to 26 mm Hg; for cell II, Rp = 0.6 μm and Po_2 was in the range of 32 to 64 mm Hg. The arrows on the solid lines indicate the sequence of pressure changes, and the dashed lines represent linear regression extrapolations of the loading phase data to Lf/Rp = 0. Note that these dashed lines have a positive P intercept, thus indicating a resistance to initial tongue formation.

Greater deformation was observed at a given P during the unloading phase than was measured at that P during loading. This hysteresis tended to be more notable at lower Po_2 and exceeded that previously observed during deformation of oxygenated, dense HbSS RBC.[8,9] The presence of hysteresis indicates that, even for the cells whose behavior we have termed "essentially elastic," the deformation response deviates from that of a true elastic material. Second, it was noted that if P was initially raised from zero in small steps, a large P was often required before membrane deformation became apparent. This large resistance to initial tongue growth is evidenced by the non-zero intercepts of the dashed lines shown in Fig 6; these lines represent extrapolation of the Lf *v* P data for the loading phase to Lf = 0. The non-zero intercepts indicate that after an initial higher resistance to deformation was overcome, tongue growth subsequently occurred more easily. Such a phenomenon could represent the existence of a yield shear stress for HbS gel deformation, the presence of strain in the resting cell membrane induced by its distortion during sickling, or the resistance of HbS polymers to initial bending. Thus, the abnormal rigidity of sickled cells could represent contributions from several mechanical abnormalities.

Smooth HbSS discocytes with unaltered morphology were present at all Po_2 levels used in the present study, although at the lowest oxygen tensions, they were only present in small numbers; in the micropipette chamber, they could be seen adjacent to sickled cells. Data for the viscoelastic characteristics of these discocytic cells are shown as functions of Po_2 in Fig 7. There was no significant correlation of either the μ or the tc for shape recovery with Po_2. All the sample means obtained for these two mechanical properties at reduced Po_2 fell within the ranges previously found for oxygenated HbSS discocyte samples.[8] Also shown in Fig 7 are data for normal HbAA RBC; these control cells were measured for Po_2 in the range of 5 to 25 mm Hg and at Po_2 = 150 mm Hg. The μ and tc values measured for these HbAA RBC at reduced Po_2 were not significantly different from those for cells equilibrated at 150 mm Hg. Thus, no changes in membrane elasticity or membrane viscosity (ie, $\eta_m = \mu \cdot \text{tc}$) were detected for HbSS RBC that maintained discocytic morphology, or for HbAA cells. Consequently, neither the resistance to deformation nor the rate of the deformation response would vary with Po_2 for these discocytic cells.

DISCUSSION

The results presented herein indicate that when morphological sickling occurs, cellular deformability becomes greatly impaired and that this impairment increases as Po_2 is lowered. Our EMR data are in general agreement with the estimate of decreased membrane deformability obtained by LaCelle[10] for sickled cells at $Po_2 < 20$ mm Hg, although the large changes in ISC rigidity noted here (Fig 4) were not detected in that study. Moreover, we have found that the response of sickled cells to deforming forces is extremely slow. These alterations in mechanical behavior parallel the changes that have been noted previously in the viscoelasticity of sickle cell suspensions and of HbS solutions as Po_2 is reduced.[14] Hence, it seems likely that the deformation response of an individual sickled cell is dominated by the viscoelastic properties of its cytoplasm.

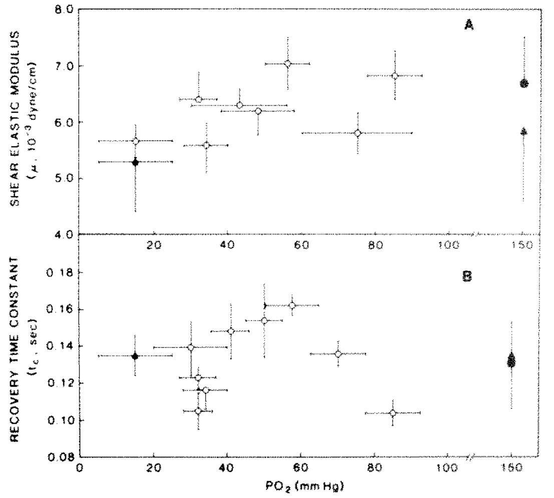

Fig 7. (A) Shear elastic modulus (μ, 10^{-3} dynes/cm), and (B) time constant for extensional shape recovery (tc, seconds) *v* Po_2 (mm Hg) for HbSS and HbAA discocytes. The horizontal bars indicate the range of Po_2 from that measured when the sample was loaded into the chamber to the higher value remeasured after micropipette analysis; all data points are located at the average of these two Po_2 measurements. Data for HbSS discocytes at $Po_2 <$ 100 mm Hg (○) are mean ± SEM for an average of 7 cells. In panel A, samples from eight donors were tested, each at a single Po_2 range; in panel B, samples from five donors were tested at one or more Po_2 ranges. Data are also shown for HbSS discocytes at Po_2 = 150 mm Hg (●) (ie, equilibrated with room air; from Nash et al.[8]) The points represent the mean ± SD of sample means from ten donors. For normal HbAA RBC (▲), points are mean ± SD of sample means from three donors. Micropipette tests were carried out at Po_2 = 150 mm Hg and in the range of 5 to 25 mm Hg for each HbAA donor. Note that for both the μ and the tc for shape recovery, neither HbSS nor HbAA RBC showed significant variations with Po_2.

As oxygen tension is reduced, formation of a sufficient amount of HbS polymer could cause the development of a new cellular elastic-resistive element and a very large increase in cytoplasmic viscosity, thus causing the cellular changes measured in the present study. The viscoelastic solid nature of this HbS polymer, and its entry into the micropipette during the deformation studies, is evidenced by the following experimental observations: (1) For cells behaving elastically (Fig 3A), membrane tongues reached a Lf rather than continuing to grow, although the aspiration pressures were too high to be supported solely by the unaltered membrane[8]; (2) in these elastic cases, deformation was recoverable when the pressure was released (Fig 6); (3) rates of tongue deformation were too slow to be the result of the flow of only the Hb solution phase into the pipette; (4) for cells showing plastic deformation (Fig 3B), the HbS within the tongue returned to the main portion of the cell if the pressure was released before budding occurred, although the membrane itself was irreversibly deformed. A nonelastic Hb solution would not return to the main portion of the cell, since there would be no driving force to cause this flow.

The above considerations suggest that the cellular deformation response will depend on the fraction of the HbS that is polymerized. In the Appendix, we describe calculations to determine polymer fraction (Fp) at 23 °C, for cells containing different HbS concentrations. The calculated plots of Fp *v* Po_2 are shown in Fig 8; superimposed are our experimental data for EMR *v* Po_2 (Fig 4) and for percentage of cells sickled *v* Po_2 (Fig 2). It can be seen that elevated rigidity occurs in the region where polymer is predicted to exist, and that EMR increases with Fp. However, there does not appear to be a simple, linear relation between EMR and Fp; there is no theoretical reason to suppose that Fp, cytoplasmic viscoelasticity, and cellular rigidity can be simply and linearly interrelated. Sickling itself appears to start at a Po_2 at which only the most dense cells [ie, hemoglobin concentration (Ct) $\gtrsim$ 40 g/dL] would contain polymer (Fig 8), but all cells are predicted to contain some polymer at the Po_2 at which 50% of the cells were observed to have sickled.

Discocytes that do not undergo sickling at a given reduced Po_2 may still contain some polymerized HbS, and it has been suggested that these cells will have impaired flow properties.[13] Indeed, changes in HbSS RBC suspension viscosity and filterability begin at oxygen tension levels higher than those at which sickling would be expected.[3,11,12] These flow abnormalities may be caused by changes in cytoplasmic viscosity which are not sufficient to affect micropipette measurements, since all discocytes measured in the present study exhibited normal rigidity and shape recovery rates. Deficiencies in cellular deformation response were detected only for those cells that had undergone changes in shape (ie, sickled forms) or surface appearance (ie, granular discs or ISC). Whether a cell sickles at a given Po_2 is likely to depend on its total Ct and/or on its content of fetal hemoglobin (HbF), since either low Ct or high HbF inhibits polymer formation.[12,25] HbF levels were measured for the donors tested in the present study and fell within the range of 0.2% to 13.1%. Based on the findings of Dover et al,[26] this range would mean that between 0.5% to 34% of the RBC would be so-called F cells; these cells contain disproportionately high levels of HbF, averaging 38% of their Ct.[26] At the lowest Po_2 levels, at which few discocytes were present, those discocytes that were subjected to micropipette analysis could preferentially be F cells. However, the discocytes tested at higher Po_2 could not all be F cells, since the percentage of discocytes exceeds the calculated proportion of F cells (see Fig 2). Whatever the mechanisms are that protect some cells from sickling, our data can be interpreted to show that enough polymer must form inside a cell to cause morphological sickling before the cell's deformability is grossly impaired.

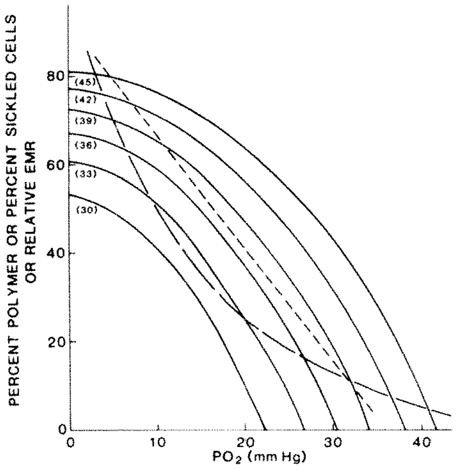

Fig 8. Calculated polymer fraction (Fp, in percentages) *v* Po_2 for HBSS RBC at 23 °C (——). Figures in brackets are the hemoglobin concentrations (Ct, g/dL) for each curve. Also shown are the lines previously fitted to the experimental data for percentages of sickled cells *v* Po_2 in Fig 2 (- - - -) and for relative effective membrane rigidity *v* Po_2 in Fig 4 (— —). Note that the relative EMR data (ie, EMR/μ) were calculated using a shear elastic modulus for oxygenated HbSS RBC (μ) taken from ref.[8]

Variations in cellular Hb concentration within samples and between donors could contribute to the experimental variability found in EMR and t½ values within individual RBC samples (ie, vertical bars in Figs 4 and 5) and between different donors tested at similar Po_2 levels. In addition to polymer formation, the viscosity of deoxygenated HbS solutions[14] and the elastic modulus of HbS gels[27] are strongly dependent on Hb concentration. Those sickled cells that deformed continuously and underwent plastic deformation may represent cells that had lower Ct and hence less severely impaired deformability. The present investigation is somewhat limited; although different cell types could readily be distinguished on the basis of their morphology or deformation response, the structural bases for these differences are not definitely known. Thus, the role of Hb concentration in determining variations in cellular deformation response at reduced Po_2 deserves further experimental studies. For example, density fractionation could be carried out prior to deformability analyses. Such a prolonged set of measurements may be more feasible if a simplified test procedure is used, eg, measuring the pressure required for total entry of cells into larger 3-μm pipettes.[10]

In contrast to the possible protective influence of low Hb concentration on the development of mechanical abnormalities, dense cells with high Hb concentration could be particularly significant in the pathogenesis of HbSS disease. These dense cells are probably the first to develop polymer-induced abnormalities as Po_2 is reduced. This suggestion regarding the possible detrimental effect of dense cells is supported by the results of the present study, in that: (1) cells with irregular surfaces (ISC and granular HbSS discocytes), which were found at reduced Po_2 levels, resembled cells found in deoxygenated dense cell fractions by Kaul et al[23]; (2) these irregular cells were present at oxygen tensions at which few spiculed, sickled cells were observed and tended to be more rigid than spiculed cells tested at comparable Po_2 levels (Fig 4).

It is not certain how closely the Po_2-dependent changes which we have measured at 23 °C reflect the changes that occur for HbSS RBC in vivo. We found that sickled cells with impaired deformability existed at $Po_2 \lesssim 40$ mm Hg. However, at 37 °C, sickling occurs at higher Po_2 levels (Fig 2). Because mixed venous blood typically has $Po_2 \sim 40$ mm Hg, and lower levels exist in some regions of the circulation, sickling probably occurs in vivo. Changes in mechanical properties, comparable to those measured in the present study, would make it highly likely that these sickled cells would obstruct narrow blood vessels.[28] Along with increased cell rigidity and decreased rates of deformation, the existence of elongated and irregular spiculed shapes could contribute to vascular occlusion. The mechanical abnormalities detected in the present study are much more severe than those we have previously found in dense oxygenated ISC and some RSC.[8] Thus, sickling may be a potentially more important cause of vascular occlusion than is the existence of some poorly deformable dense oxygenated cells, although the latter have been suggested to play a role in initiating the occlusive process.[4,28,29]

ACKNOWLEDGMENT

The authors wish to thank Dr Constance T. Noguchi for suggestions regarding the calculation of HbS polymer fraction, and for helpful discussions of the polymerization process. We also gratefully acknowledge the technical assistance of Rosalinda Wenby and Victoria Lovelace.

APPENDIX

The fraction of polymerized hemoglobin (Fp) inside an HbSS RBC which contains a total hemoglobin concentration (Ct) is given by: $Fp = Cp \cdot (Ct - Cs)/Ct \cdot (Cp - Cs)$, where Cs is the HbS solubility and Cp is the polymer concentration of 69 g/dL.[30] Sunshine et al[31] have measured the solubility of HbS at 23 °C for various solution phase oxygen saturations (Ysol). Using the above equation and their data for Cs, Fp was calculated as a function of Ysol. To determine the variation of polymer fraction with Po_2, the relation between Ysol and Po_2 at 23 °C was required; this is not the same as the oxygen saturation of HbSS cells, since cells can contain a mixture of HbS solution and polymer. However, oxygen saturation *v* Po_2 data for normal HbAA blood can be used to represent the oxygen affinity of HbS in the solution phase (ie, Ysol *v* Po_2), since HbS and HbA have the same oxygen affinity when in solution.[32] Using oxygen affinity data for HbAA RBC at 23 °C,[33] polymer fraction *v* Po_2 relations were calculated for various total cellular hemoglobin concentrations (ie, Ct) at 23 °C. The predicted Fp *v* Po_2 curves are shown in Fig 8 for a chosen set of Ct. They indicate, for example, that at 23 °C, HbS polymer formation starts at a Po_2 of ~35 mm Hg for cells with Ct $\gtrsim$ 39 g/dL, and at about 20 mm Hg for cells with Ct $\lesssim$ 30 g/dL.

High Molecular Weight Kininogen: Localization in the Unstimulated and Activated Platelet and Activation by a Platelet Calpain(s)

By Alvin H. Schmaier, Paulette M. Smith, A. David Purdon, James G. White, and Robert W. Colman

High mol wt kininogen (HMWK), the major cofactor-substrate of the contact phase of coagulation, is contained within and secreted by platelets. Studies have been performed to localize platelet HMWK in both the unstimulated and activated platelet and to ascertain the effect of platelet enzymes on HMWK itself. On platelet subcellular fractionation, platelet HMWK was localized to α-granules, and platelets from a patient with a deficiency of these granules (gray platelet syndrome) had 28% normal platelet HMWK. Platelet HMWK, in addition to being secreted from the platelet, was also localized to the surface of the platelet when activated. Using a competitive enzyme-linked immunosorbent assay for HMWK as an indirect antibody consumption assay, the external membrane of thrombin-activated platelets as well as the releasate from these stimulated platelets had 17 ng HMWK antigen/10^8 platelets available, whereas unstimulated platelets and their supernatant had only 4.9 and 4.2 ng HMWK/10^8 platelets present, respectively. The anti-HMWK antibody consumption by activated normal platelets was specific for membrane-expressed platelet HMWK, since activated platelets from a patient with total kininogen deficiency did not adsorb the anti-HMWK antibody. Enzymes in the cytosolic fraction of platelets cleaved ^{125}I-HMWK (mol wt 120,000) into a mol wt 100,000 polypeptide as well as smaller products at mol wt 74,000, mol wt 62,000, mol wt 47,000, and a few components below mol wt 45,000. No cleavage products were observed when DFP and leupeptin were present. The cleavage of HMWK was specifically prevented by inhibitors of calcium-activated cysteine proteases (leupeptin, *N*-ethylmaleimide, iodoacetamide, and EDTA) but not by inhibitors of serine proteases (DFP, benzamidine, soybean trypsin inhibitor, or aprotinin). Platelet cytosol increased the coagulant activity of exogenous purified HMWK with maximum HMWK coagulant activity (35-fold) occurring within ten minutes of exposure to platelet cytosol. Treatment of platelet cytosol with leupeptin prevented the increase in the coagulant activity of exogenous HMWK. These studies indicate that activated platelets express platelet HMWK on their external membrane and platelet enzymes can cleave and increase the coagulant activity of exogenous HMWK.

HIGH MOL WT kininogen (HMWK) is the major cofactor for contact phase zymogen (factor XII, prekallikrein, factor XI) activation as well as their major substrate. Recent studies suggest that plasma HMWK may be a procofactor which, when cleaved, may elaborate higher surface-mediated cofactor activity. Bovine intact HMWK, kinin-free kininogen, and a large fragment consisting of fragment 1 · 2 and light chain accelerate the generation of factor XII and kallikrein activity on a kaolin surface, whereas kinin and fragment 1 · 2 free protein, heavy chain, or low mol wt kininogen do not.[1] Further studies show that kallikrein-cleaved bovine HMWK, preceding kinin liberation, accelerates kaolin-mediated activation of bovine factor XII over intact HMWK.[2] The accelerating effect of cleaved bovine HMWK on factor XII activation is mediated through its adsorption on the kaolin surface through the fragment 1 · 2 region and its complex formation with prekallikrein through the light chain region.[3] More recent studies with human HMWK indicate that the amount of HMWK adsorbed to kaolin is closely correlated with its coagulant activity, and the ability of HMWK to adsorb to kaolin increased with time of kallikrein digestion to a maximum, paralleling bradykinin liberation.[4] These studies suggest that HMWK is a procofactor whose cleavage by kallikrein activates the molecule, allowing enhanced coagulant activity and bradykinin liberation.[4]

Our finding that platelets contain HMWK, a fourth cofactor in plasma coagulation reactions which is secreted after platelet activation,[5] suggest that platelets may provide an in vivo activating surface. To characterize the ways in which platelet HMWK and platelets themselves may contribute to contact phase activation, a study was initiated to determine the location of platelet HMWK in unstimulated and activated platelets and to determine whether platelet enzymes alter HMWK. This work shows that platelet HMWK is a platelet α granule protein in the unstimulated platelet that is expressed on the activated platelet membrane after thrombin stimulation. Moreover, platelets contain a calcium-activated cysteine protease [Calpain(s)] which can cleave the procofactor HMWK and, concommitant with this cleavage, increase its coagulant activity.

MATERIALS AND METHODS

Materials. Antiserum to fibrinogen was purchased from Atlantic Antibodies, Scarborough, Me. Nagarse was purchased from the Enzyme Development Corp, New York. Human α thrombin (3209 NIH U/mg) was a kind gift of Dr J. Fenton, New York State Department of Health, Albany, NY. Na ^{125}I (50 mCi/mmol) was obtained from New England Nuclear, Boston. Iodogen (chloroamide, 1,3,4,6-tetrachloro-3 α-6 α-diphenyl glycoluril) was obtained

from Pierce Chemical Co, Rockford, Ill. Standards for mol wt determination on polyacrylamide gels in sodium dodecyl sulfate (SDS) were purchased from BioRad Corp, Richmond, Calif. Antisera to bradykinin was a generous gift of Dr David Proud, Johns Hopkins University, Baltimore, Md. All other reagents were obtained from Sigma Chemical Corp, St Louis, Mo.

Plasma and Platelets. Pooled normal plasma (lot No. 120 and N10) was purchased from George King Biomedical, Inc, Overland Park, Kan. These lots of plasma were previously determined to contain 80 and 88 μg/mL, respectively, of HMWK antigen by comparison of the plasma antigen to purified HMWK reconstituted into total kininogen-deficient plasma.[5] HMWK antigen was assayed by electroimmunodiffusion using monospecific antisera to the light chain of HMWK.[5] Total kininogen-deficient (ie, deficient in both HMWK and low mol wt kininogen) plasma[6] and platelets[5] were donated by Mrs M. Williams, Philadelphia, Pa. Platelets from a patient (R.K.) with the gray platelet syndrome[7] was directly donated to this laboratory. This patient had a plasma HMWK level of 63 μg/mL as determined by electroimmunodiffusion.[5] Normal donors, who provided written informed consent, were young men and women (ages 21 to 40) on no medication. Fresh blood was collected, and platelet-rich plasma and platelet-poor plasma were prepared as previously described.[8] In the experiments with the platelet calcium-activated protease (Calpain), supernatants of lysed platelets refers to a 12,000 g supernatant of frozen and thawed platelets. In these same experiments, cytosols of lysed platelets refers to a 100,000 g supernatant of frozen and thawed platelets. Elsewhere in the text, use of the term supernatant of platelets simply refers to the soluble material obtained after centrifugation.

Preparation of HMWK. HMWK was purified from fresh plasma using a modified procedure of Kerbiriou and Griffin[9] that included 0.2 mol/L of ϵ amino caproic acid in all buffers and 2 mmol/L of diisopropylfluorophosphate (DFP) added to the pooled HMWK prior to each step in the purification procedure. ϵ Amino caproic acid was added to the buffers of the purification to prevent the possibility of plasmin proteolysis of the HMWK during the purification procedure.[10] This preparation of HMWK, reduced on 7.5% polyacrylamide gel electrophoresis (PAGE) with SDS,[11] was a single band of mol wt 120,000. The specific activity of the purified HMWK varied from 12 to 20 U/mg. HMWK coagulant activity was measured by a one-stage kaolin-activated assay using total kininogen-deficient plasma as substrate[6] as described previously.[5] In brief, samples were compared against a daily standard curve from pooled normal human plasma diluted in 0.01 mol/L of Tris-HCl, 0.15 mol/L of NaCl, pH 7.4. The final dilutions of plasma ranged from 1/10 to 1/1,000 and were linear on a log–log plot. One unit was defined as the amount in 1 mL of pooled normal plasma.

Purified HMWK was radiolabeled with $Na^{125}I$ using Iodogen by the method of Fraker and Speck[12] as previously reported.[5] The radiolabeled protein was >95% trichloroacetic acid precipitable and retained >95% of its procoagulant activity as well as its antigenic properties. The specific radioactivity of the preparations of ^{125}I-HMWK used in these studies varied from 1 to 5 μCi/μg. Protein determinations were performed by the method of Bradford[13] using crystalline bovine serum albumin as the standard.

Anti-HMWK Antisera. Goat antisera directed against the light chain of HMWK were prepared from total kininogen antisera by successive adsorption with purified low mol wt kininogen as previously reported.[5,14] The monospecific antisera to the light chain of HMWK was used in a competitive enzyme-linked immunosorbent assay (CELISA).[5]

Localization of Platelet HMWK in the Unstimulated Platelet. Platelet subcellular fractionation was performed according to the technique of Fukami et al.[15] In each preparation, platelet-rich plasma from 450 mL of blood was collected, adjusted to contain 5 mmol/L of EDTA and pelleted by centrifugation at 3,000 g for ten minutes at 4 °C. The platelet pellet was suspended in 30 mmol/L of Hepes, 5 mmol/L EDTA and 0.15 mol/L of NaCl, pH 6.5. After being washed by two additional centrifugations at 3,000 g for ten minutes at 4 °C, the pellet was resuspended in 40 mL of the same medium containing 20 μmol/L of rotenone, 5 mmol/L of 2-deoxy-D-glucose and 10 mmol/L of D-gluconic acid δ lactone and was incubated at 37 °C for 20 minutes. Then, 3 mg of nagarse and 20 mg of ATP were mixed into the suspension at 37 °C. Five minutes later, 20 mg of soybean typsin inhibitor was added to neutralize the nagarse, and the platelets were centrifuged at 3,000 g for ten minutes at 4 °C. The pellet was then resuspended into 25 mL of 0.01 mol/L of Hepes, 1 mmol/L of EDTA, and 0.25 mol/L of sucrose, pH 7.4, and was homogenized twice in a French pressure cell[16] at 500 lb/sq in with one centrifugation in between so that only the unbroken cells were subjected to the second homogenization. Five milliliters of the combined homogenate was set aside, and 20 mL were used for fractionation. Differential centrifugation of the homogenate resulted in the isolation of four fractions: the F_1, which consists of unbroken platelets and large fragments, is a 1,000 g × 22-minute pellet; F_2, which contains platelet granules and mitochondria, is a 12,000 g × 20-minute pellet; F_3, which contains platelet membranes, is a 100,000 g × 60-minute pellet; and F_4, which is platelet cytosol, is a 100,000 g supernate. The granule fraction, F_2, was then divided in half and one half was applied to a 0.8 to 2.0 mol/L sucrose discontinuous step gradient in 0.2 mol/L increments.[17] After centrifugation at 100,000 g for 60 minutes, five distinct zones were collected: zone A, 0.25 to 1.0 mol/L of sucrose; zone B, 1.0 to 1.3 mol/L of sucrose; zone C/D, 1.3 to 1.8 mol/L of sucrose; zone E, 1.8 to 2.0 mol/L of sucrose; and zone F, the pellet. Radiolabeled HMWK tracer experiments were performed to determine that the measured HMWK in the granule fractions arose from those fractions and was not merely soluble plasma HMWK attached to or trapped in the granule material. Prior to assay, fractions F_4 and A through E of the F_2 were dialyzed against 0.01 mol/L of Hepes, 1 mmol/L of EDTA, pH 7.4, lyophilized, and resuspended in 5 mL of the dialysis buffer. Fractions were treated with 0.5% Triton X-100 prior to assay. HMWK antigen was assayed by CELISA using antisera directed to the light chain of HMWK.[5] The CELISA for HMWK used to determine the amount of HMWK in the total and each fraction of the subcellular fractionation of platelets was performed identically as previously described.[5] A standard competitive inhibition curve was obtained with normal plasma and plotted by a computer-fitted four-parameter logistic function.[18] The amount of HMWK in each part of the subcellular fractionation was obtained from the calculated slope of a linear regression generated by multiple dilutions of the unknown sample.[18] β-*N*-acetylglucosaminidase was assayed by the technique of Day et al.[19] Fibrinogen was assayed by electroimmunodiffusion.[20] Platelet serotonin was assayed by the technique of Weissbach et al.[21] Only preparations that had a recovery >60% for total protein, HMWK, fibrinogen, β-*N*-acetylglucosaminidase, and serotonin were used in the analysis. The "relative specific amounts" of each marker in the preparations were calculated from the ratio of the "specific amount" of the marker in the fraction (amount of antigen or activity per milligram of total protein) (F_1 through F_4; A through P) to the specific amount of the marker in the total platelet homogenate or F_2 fraction, respectively. The percentage of distribution of each protein in each fraction was determined by the ratio of the area under the bar graph for each fraction (relative specific amount times total protein) to the area of the sum of all fractions in either the differential centrifugation or sucrose density ultracentrifugation.

Studies on the total content of platelet HMWK in gray platelets and a concomitant normal control were done on blood anticoagulated with 3.8 g/dL sodium citrate containing PGE_1 (final concentration 1 μmol/L). After the platelet-rich plasma was separated,[8] washed platelets were obtained by the combined techniques of albumin density gradient centrifugation and gel filtration with buffer containing 1 μmol/L of PGE_1 performed as previously reported.[5] PGE_1 was added to the anticoagulant and gel filtration buffer to prevent loss of platelet HMWK during the washing procedure. The washed platelets were solubilized by the addition of Triton X-100 (0.5% final concentration) at room temperature for 30 minutes. The total platelet HMWK in these samples was assayed by CELISA performed identically as was previously reported.[5]

Localization of platelet HMWK in the Activated Platelet. Studies were performed to determine if platelet HMWK was detectable on the surface of activated platelets. Four hundred fifty milliliters of fresh blood from two donors was collected into 73 mmol/L of citric acid, 3 mmol/L of trisodium citrate containing 2% dextrose (1:10) (ACD), and platelet-rich plasma was obtained.[8] After the pH was adjusted to 6.5 with 1 mol/L of citric acid, the platelet-rich plasma was washed twice by the centrifugation technique of Mustard.[22] The Tyrode's buffer containing Ca^{2+} (2 mmol/L) and Mg^{2+} (1 mmol/L) had both apyrase and heparin (12.5 U/mL) in the first wash and apyrase alone in the second wash. Apyrase was prepared from potatoes by the method of Molnar and Lorand[23] and was titered so that the minimal amount necessary to prevent second-wave platelet aggregation with ADP was used. The final washed platelets were resuspended in Hepes buffer[24] to a total volume of 10.5 mL. In four experiments, the platelet concentration ranged from 1.75 to 8.8×10^9 platelets per milliliter. These platelet preparations contained $<0.05\%$ red cells and $<0.03\%$ leukocytes (monocytes, granulocytes and lymphocytes, combined). The washed platelets were then divided into three aliquots, each of 3.5 mL. Two aliquots received PGE_1 (final concentration 1 μmol/L) and were incubated for 40 minutes at 37 °C. The third aliquot was made to 0.4 mmol/L with Gly-Pro-Arg-Pro in order to prevent fibrin polymerization and platelet aggregation of activated platelets[25] and was placed in a flat-bottomed polystyrene tube in a 37 °C water bath. Thrombin (0.5 U/mL) was introduced, and the reaction was allowed to proceed for ten minutes without stirring. Immediately after the ten-minute incubation with thrombin, the contents of the tube were layered on a 2.5-ml discontinuous albumin density gradient (10%, 15%, 20%, 30%, 40%) prepared as previously reported.[5] After centrifugation at 2,000 rpm for 25 minutes at 23 °C in a GLC-2B centrifuge (Dupont Instruments, Wilmington, Del), 3.5 mL of activated platelet supernatant was separated from the activated platelets, which formed a layer over the 40% albumin cushion. The platelets were resuspended in 3.5 mL of Hepes buffer containing 0.4 mmol/L of Gly-Pro-Arg-Pro. A second platelet aliquot was centrifuged for four minutes at 12,000 g in an Eppendorf centrifuge (Brinkman Instruments, Inc, Waterbury, Conn), and the supernatant was collected. Thus, four specimens were collected: an aliquot of intact, unstimulated platelets, supernatant from unstimulated platelets, thrombin-activated platelet supernatant, and thrombin-activated platelets.

The platelet samples were prepared for use in a modified CELISA for HMWK as an indirect antibody consumption assay. Because membrane-expressed platelet HMWK would not be soluble to allow a direct determination of its presence, and solubilization of activated platelets would liberate intracellular platelet HMWK, an experimental design was developed to determine if surface-expressed platelet HMWK could be detected when whole platelets were incubated with the antisera directed to HMWK. Conditions for this antibody consumption assay for surface-expressed platelet HMWK were developed so that intraplatelet HMWK (that which was neither secreted nor expressed on the external membrane) would not interfere. The four platelet specimens were mixed with an equal volume of monospecific anti-HMWK antisera (final concentration 1:500). This antisera had previously been diluted 1:250 in 0.01 mol/L of sodium phosphate pH 7.4, 0.15 mol/L of NaCl containing 0.05% Tween-20 (PBS-Tween), and was also made 1:250 with total kininogen-deficient plasma. Before the prepared antisera was mixed with the platelet material, the antisera was ultracentrifuged at 100,000 g for 90 minutes in a Beckman Model L3-50 ultracentrifuge (Beckman Instruments, Inc, Palo Alto, Calif) to remove any aggregates that might be present. The total kininogen-deficient plasma was added to the incubation mixture to prevent nonspecific association of goat anti-HMWK IgG to human platelet Fc receptors by the addition of excess human IgG. After the four platelet samples were combined with the antisera, each mixture was incubated for one hour at 37 °C. In preliminary experiments, a one-hour incubation of purified HMWK or HMWK in normal plasma was sufficient to achieve $>$ a 90% interaction of soluble antigen and antibody when compared to a two- to three-hour incubation at 37 °C. At completion of the incubation, each specimen was centrifuged at 12,000 g in an Eppendorf centrifuge, and the supernatants were collected. Aliquots for lactic dehydrogenase determination[26] were taken from each of the four supernatant specimens to be compared to the amount of lactate dehydrogenase lost by solubilization of intact platelets by addition of 0.5% Triton X-100.

Four antibody samples per experiment were then compared by a CELISA assay for HMWK[5] using known amounts of purified HMWK antigen to determine the slope of the competitive inhibition curve produced by each batch of platelet-adsorbed or platelet supernatant-adsorbed antisera. The competitive inhibition curves generated on the CELISA by the four aliquots of adsorbed antisera were produced by the method of incubation of samples as previously reported.[5] However, since the aim of the assay was to determine whether the titer of the antisera would be decreased (consumed) by incubation with platelets or their supernatants, the final competitive inhibition curves were analyzed by nonlinear regression to determine the slope of the competitive inhibition curve produced by antisera adsorbed with each of the aliquots of platelet material. In all experiments, the differently adsorbed aliquots of antisera were reacted with the same amounts of purified HMWK (1 to 125 ng). The data were plotted as the concentration of the purified HMWK used to determine the slope of the competitive inhibition curve of the adsorbed antisera on the abscissa *v* the optical density at 405 nm on the ordinate. The measured value of this assay was the slope of the competitive inhibition curve. Statistical comparison of the differences of the slopes of the competitive inhibition curves was performed by grouped paired T test.

Quantification of the amount of platelet HMWK expressed on the surface of the platelet was obtained by comparing the values of the slopes produced by each sample of platelet-adsorbed or platelet supernatant-adsorbed antisera with a standard curve of the anti-HMWK antisera adsorbed with known concentrations of purified HMWK. In these latter experiments, the anti-HMWK antisera was was adsorbed by purified HMWK at various concentrations (20 to 2,000 ng/mL) for one hour at 37 °C. After incubation, the adsorbed antisera was interacted with purified HMWK to determine the adsorbed antisera's competitive inhibition curve. These slopes were also calculated by nonlinear regression. The data from these latter experiments were plotted as concentration of purified HMWK used to adsorb the antisera on the abscissa *v* the slope of the resultant competitive inhibtion curve on the ordinate. The amount of HMWK (plasma or platelet) associated with the surface of the platelet or in its suspending medium was estimated by comparing the slopes of the competitive inhibition curve produced by the antisera adsorbed with the platelet material with the slopes of the competitive inhibition curves produced by known concentrations of purified HMWK. The final results were calculated based on the number of platelets in each experiment and were expressed as nanogram of HMWK per 10^8 platelets.

Platelet proteolysis and activation of purified HMWK. The effect of supernatants and cytosols of platelet lysates on purified exogenous ^{125}I-HMWK and nonradiolabeled HMWK was studied. Platelets from 450 mL of blood were washed by the centrifugation technique of Mustard,[22] and the final washed pellet was resuspended in 1 to 2 mL of Hepes buffer[24] without bovine serum albumin and dextrose, or in 0.1 mol/L of Tris, 0.15 mol/L of NaCl, pH 7.4 (TBS) with or without 1 mmol/L of EDTA. After the platelet suspension was made hypotonic by addition of 0.5 to 1 mL of deionized water, the platelets were lysed by freezing and thawing four times on dry ice and at 37 °C. The supernatants of the lysed platelets were collected after centrifugation at 12,000 g in an Eppendorf centrifuge. In certain experiments, the supernatant of the platelet lysate was ultracentrifuged at 100,000 g for 90 minutes at 4 °C to collect a platelet cytosol. Supernatant and cytosol of lysed platelets were used to study the effect of platelet enzymes on ^{125}I-HMWK and exogenous HMWK. In certain experiments, the platelet lysate or cytosol was preincubated with cysteine or serine protease inhibitors for 10 to 30 minutes prior to the addition of the HMWKs. In experiments in which the platelet cytosol was prepared in the presence of 1 mmol/L of EDTA, the reaction was begun by the addition of 2.5 mmol/L of $CaCl_2$. All incubation mixtures of the platelet material and the HMWKs were performed at 37 °C. Determination of cleavage of exogenous ^{125}I-HMWK by platelets was performed by reducing a 25 to 50-μL aliquot of the platelet supernatant–cytosol–^{125}I-HMWK mixture with 2% β mercaptoethanol and adding it to a 7.5% polyacrylamide gel with SDS for electrophoresis. Detection of changes in the ^{125}I-HMWK was made by performing autoradiography on the dried gel. Determination of changes in activity of exogenous purified HMWK was made by coagulant assay[5] of the HMWK-platelet supernatants or cytosol mixtures. Bradykinin release from exogenous HMWK added to platelet cytosol was measured by radioimmunoassay performed as previously reported.[4]

RESULTS

Localization of platelet HMWK in the unstimulated platelet. Platelet subcellular fractionation studies were performed to determine the platelet location of platelet HMWK in the resting platelet. Six aliquots of washed platelets were evaluated for the subcellular localization of platelet HMWK by differential centrifugation (Fig 1). In these six preparations, the recovery (mean ± SEM) of total protein was 76% ± 3.2%; of HMWK antigen, 92% ± 9.5%; of fibrinogen antigen, 79% ± 14%; and of β-*N*-acetylglucosaminidase activity, 88% ± 5.8%. Radiolabeled HMWK tracer studies for the differential centrifugation separation were performed by the introduction of the ligand into the platelet homogenate after platelet lysis by the French Press. In these studies, 95.5% of the tracer was recovered in the F_4 cytosol fraction, 3.8% of the tracer was found in the F_3 membrane fraction, 0.4% of the tracer was found in the F_1 fraction, and only 0.3% of the tracer was localized to the F_2 granule/mitochondria fraction. When washed, lysed platelets were subjected to differential centrifugation, the largest amount (46% of the total antigen), as indicated by the area under the bar graph, of platelet HMWK antigen was found in the 12,000 g pellet (fraction F_2) (Fig 1). This localization of platelet HMWK to the F_2 fraction, a fraction previously characterized as enriched in platelet granules and mitochondria,[16] was similar to the subcellular localization found for two known platelet granule constitutents, fibrinogen and β-*N*-acetylglucosaminidase.

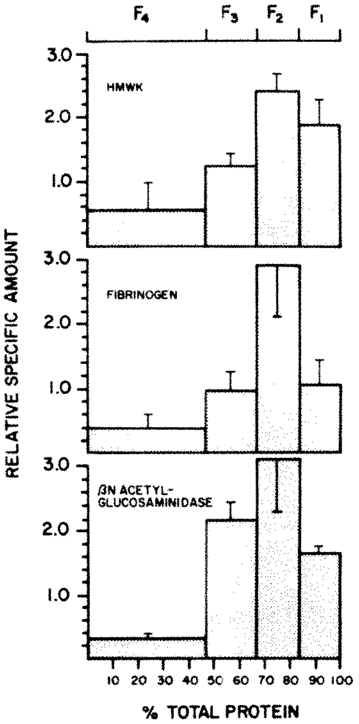

Fig 1. Platelet subcellular fractionation by differential centrifugation. Ordinate, the relative specific amount of each marker; abscissa, percentage of total protein in each fraction. The relative specific amount is the ratio of the specific amount in each fraction compared with the specific amount in the total homogenate of the platelets. The specific amount in a fraction or total is calculated by the ratio of the total antigen or activity in a fraction divided by the total protein in the fraction. The data plotted represent the mean ± SEM and the SEM is represented by the bars (T) of six experiments. F1, 1,000 g pellet; F2, 12,000 g pellet; F3, 100,000 g pellet; and F4, 100,000 g supernatant.

In an attempt to separate the components of the granule fraction further, the F_2 was subjected to sucrose density ultracentrifugation (Fig 2). In six experiments, the recovery (mean ± SEM) of total protein was 88% ± 2.6%; of HMWK antigen, 92% ± 7.8%; of fibrinogen antigen, 96% ± 10.5%; of β-*N*-acetylglucosaminidase, 80% ± 2.5%; and 98% ± 4.5% of serotonin. Radiolabeled HMWK tracer studies were also performed for the sucrose density gradient centrifugation separation with the presence of the ligand in the F_2 fraction. In these studies, 68% of the tracer remained in the soluble A fraction, 24% of the tracer was found in the C/D fraction, 4% of the tracer was found in the B fraction, 2.4% of the tracer was in the E fraction, and 1.5% of the tracer was trapped in the P fraction. Most platelet HMWK antigen entered the gradient (ie, was localized to fractions B through P, which indicated that it was in granules), and was found to be present in the largest amount, as indicated by the area under the bar graph, in the C/D and E fractions (Fig 2), fractions enriched with platelet α-granules.[15,17] The C/D fraction

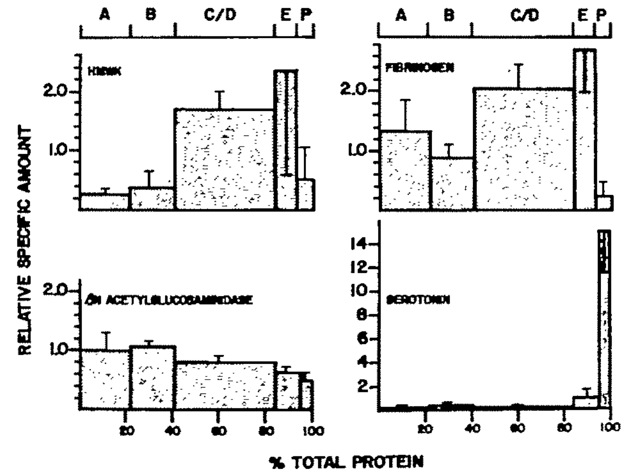

Fig 2. Further fractionation of F2 from Fig 1 by sucrose density ultracentrifugation. The data plotted represent the mean SEM and the SEM is represented by the bars (T) of six experiments. All data are plotted as in Fig 1. A, supernatant to 1 mol/L of sucrose; B, 1 to 1.3 mol/L of sucrose; C/D: 1.3 to 1.8 mol/L of sucrose; E: 1.8 to 2.0 mol/L of sucrose; F, the 100,000 g pellet of the gradient.

accounted for 65% of the total platelet HMWK, but only 44% of the total protein found in the F_2 fraction. Although 24% of the soluble ^{125}I-HMWK tracer was found in the C/D fraction, the amount of trapped soluble HMWK in this fraction was really only 0.072% of the total HMWK measured since the F_2 fraction only contained 0.3% of the soluble HMWK. This finding by the radiolabeled tracer studies indicated that most of the HMWK antigen measured in the C/D fraction must have been derived from platelet granules. This localization of platelet HMWK was similar to that of platelet fibrinogen, a known platelet α-granule constituent.[27,28] β-*N*-acetylglucosaminidase, a lysosomal granule marker enzyme, was spread throughout the gradient, and serotonin, a dense granule constituent, was concentrated in the 100,000 g pellet (P). These combined studies suggested that platelet HMWK was mostly a platelet α granule protein in the unstimulated platelet.

To confirm independently that most platelet HMWK in the unstimulated platelet was localized to platelet α-granules, platelets from a patient (R.K.) with the gray platelet syndrome[7] were studied for their total content of platelet HMWK. These platelets contained 16 ng/10^8 platelets total platelet HMWK, whereas a concomitant normal platelet control contained 52 ng/10^8 platelets. Comparing the value of total platelet HMWK in gray platelets with the normal control and nine previously determined values[5] for total platelet HMWK in normal platelets (60 ng ± 24/10^8 platelets), the gray platelets studied contained only 28% of the content of platelet HMWK.

Localization of platelet HMWK in the activated platelet. Studies were initiated to determine whether platelet HMWK became expressed on the external platelet membrane after activation. Platelets, in an unstimulated or activated state, along with their respective suspension buffers, were compared using a modified CELISA for HMWK antigen as an indirect antibody consumption assay. Anti-HMWK antisera was adsorbed with unstimulated or activated platelets and their supernatants to determine whether the titer of free anti-HMWK antibody (initial dilution 1:500) would be decreased. The detection of a decrease in the titer of the specific antibody was determined by a change in the slope of a competitive inhibition curve produced by the adsorbed antisera from each platelet aliquot when subsequently reacted with the same amounts of purified HMWK. In preliminary experiments, competitive inhibition curves produced by increasing dilution (1/500, 1/800, 1/1,100, and 1/1,500) of anti-HMWK antisera incubated with identical amounts of purified HMWK resulted in a flattening (decrease in the slope) and a shift to the left of the competitive inhibition curve as the dilution of anti-HMWK antisera was increased from 1/500 to 1/1,500 (data not shown). The relationship between the change in the calculated slope of the competitive inhibition curve produced by anti-HMWK antisera adsorbed with exposed HMWK antigen was studied in a quantitative manner (Fig 3). Anti-HMWK antisera initially

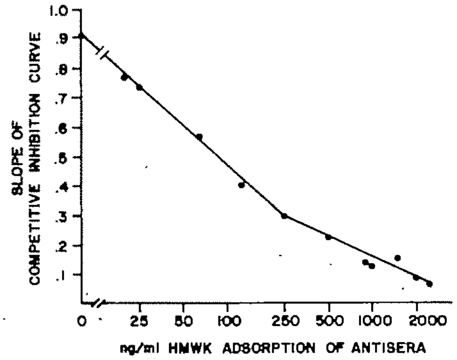

Fig 3. The relationship of the slope of the competitive inhibition curve produced by anti-HMWK antisera *v* the concentration of HMWK used to adsorb the antisera. Anti-HMWK antisera was prediluted 1:500 in PBS-Tween and incubated for one hour at 37 °C in the absence or presence of purified HMWK at a concentration from 20 to 2,000 ng/mL in the suspending buffer. At the conclusion of the 1-hour incubation, the adsorbed antisera was incubated overnight at 37 °C with an equal volume of purified HMWK in an absolute amount from 1 to 125 ng. The next day, the contents of the above incubations were added to radioimmunoassay-grade bovine serum albumin-coated (0.2%) polystrene cuvette wells that had been linked with 150 ng of purified HMWK in 0.1 mol/L of sodium carbonate, pH 9.6. After two-hour incubation and after the cuvettes were washed with PBS-Tween, the free anti-HMWK antibody, which had not been previously consumed by the two incubations with soluble HMWK and which had bound to the HMWK linked to the cuvette well, was exposed to a rabbit anti-goat antibody conjugated with alkaline phosphatase. After a further two-hour incubation, the amount of anti-HMWK antibody bound to the cuvette wells was detected by the addition of 0.05 mol/L of sodium carbonate, pH 9.8, containing 1 mmol/L of MgCl and 1 mg/mL *p*-nitrophenylphosphate disodium. The hydrolysis of the substrate was stopped at 30 minutes by the addition of an equal volume of 2 mol/L of NaOH to the volume already contained in the cuvette wells. The inhibition curves produced by the unadsorbed and adsorbed antisera were calculated by nonlinear regression. The calculated slope of the adsorbed antisera was plotted on the ordinate and the concentration of purified HMWK used to adsorb the antisera for one hour was plotted on the abscissa. Each point represents the mean of two or three experiments.

diluted 1:500 produced a competitive inhibition curve with a calculated slope by nonlinear regression of 0.9. Incubating the anti-HMWK antisera initially diluted 1:500 in separate aliquots with increasing concentrations of purified HMWK (20 to 2,000 ng/mL) for one hour at 37 °C resulted in competitive inhibition curves with reduced calculated slopes (0.77 to 0.06) (Fig 3). This study indicated that the slope of a competitive inhibition curve produced by antisera adsorbed under the identical conditions could be used to calculate the amount of exposed HMWK antigen indirectly.

Unstimulated and activated platelets and their supernatants were incubated with anti-HMWK antisera initially diluted 1:500. In one representative experiment (Fig 4), the competitive inhibition curves produced by antisera adsorbed with the supernatant of unstimulated platelets (slope 0.34) and unstimulated platelets (slope 0.33) themselves gave parallel and almost superimposable curves as previously reported.[5] The competitive inhibition curve produced by antisera adsorbed with the activated platelet supernatant was flattened with a decreased slope (0.20) when compared with that produced by the supernatant of unstimulated platelets (Fig 4). Because platelet HMWK is secreted by thrombin-activated platelets,[5] this finding indicated that secreted platelet HMWK adsorbed and decreased the titer of the anti-HMWK antibody. The competitive inhibition curve produced by activated platelets (slope 0.26) was similar to the curve that characterized the material released by platelets (Fig 4). Antisera adsorbed with activated platelets showed a competitive inhibition curve that had a reduced slope and was left-shifted when compared with unstimulated platelets. This adsorption of the antisera by activated platelets could not be owing to platelet HMWK lost from cell lysis, because the amount of lactic dehydrogenase loss under the conditions of the experiments was $<5\%$. This result suggested that some of the platelet HMWK, in addition to being secreted, must also have been expressed on the external membrane of the activated platelet.

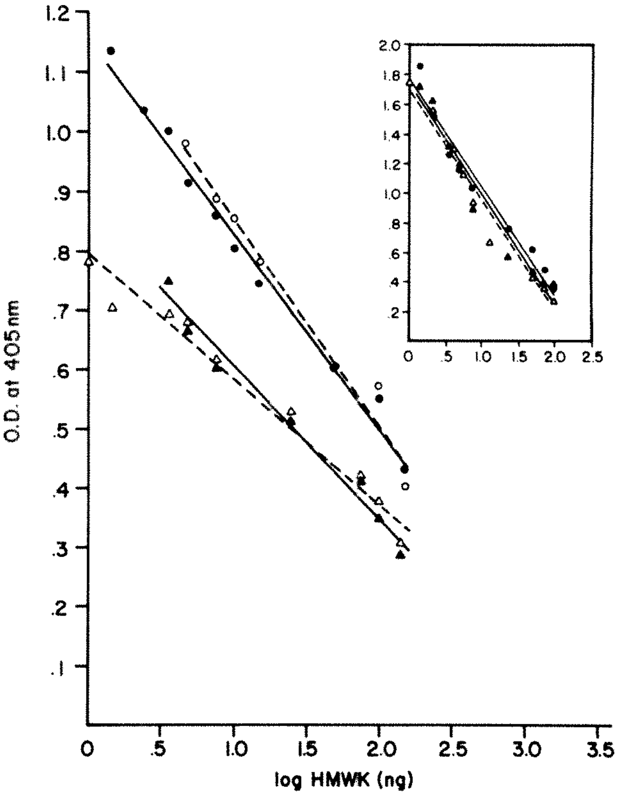

Fig 4. Expression of platelet HMWK antigen on the activated platelet surface. The competitive inhibition curves produced by anti-HMWK antisera adsorbed with unstimulated platelet supernatant (O---O), unstimulated platelets (●——●), activated platelet supernatant (Δ---Δ), and activated platelets (▲——▲) are plotted. Ordinate, observed optical density (OD) at 405 nm; abscissa, absolute amount (log HMWK in ng) of purified HMWK incubated with the prepared antisera. One representative experiment of four with normal platelets is depicted. Inset: competitive inhibition curves produced by anti-HMWK antibody consumed by total kininogen-deficient platelets. The competition inhibition curves produced by anti-HMWK antisera adsorbed with unstimulated (●——●) and activated (▲---▲) total kininogen-deficient platelets as well as the activated platelet supernatant of total kininogen-deficient platelets (Δ---Δ) are plotted. All data in the inset are plotted as above. In both plots, the competitive inhibition curves were calculated by nonlinear regression.

In four experiments, the slopes of the competitive inhibition curves produced by each of the four platelet aliquots in each experiment were calculated by nonlinear regression. Anti-HMWK antisera adsorbed by unstimulated platelets and unstimulated platelet supernatant produced competitive inhibition curves with calculated slopes (mean ± SEM) of 0.37 ± .015 and 0.37 ± .011, respectively. The slopes produced by antisera adsorbed by unstimulated platelets and supernatants from unstimulated platelets in each experiment were not significantly different ($P > .45$). Anti-HMWK antisera adsorbed by activated platelets and activated platelet supernatant produced competitive inhibition curves with calculated slopes (mean ± SEM) of 0.22 ± .027 and 0.21 ± .017, respectively. The slope produced by antisera adsorbed by activated platelets and their supernatants was not significantly different ($P > .4$). However, the slopes produced by supernatants from activated platelets and activated platelets themselves were significantly decreased ($P < .0125$, $P < .005$, respectively) when compared to unstimulated platelets. This finding indicated that both specimens had adsorbed the antibody with expressed platelet HMWK. Because the slope of the competitive inhibition curve produced by adsorbed antisera is directly related to the concentration of HMWK available to consume the specific antibody (Fig 3), an estimate of the amount of HMWK associated with each of the platelet aliquots was calculated based on the number of platelets in each experiment. In the four experiments, unstimulated platelets and their supernatant had a mean of 4.9 ng HMWK/10^8 platelets and 4.2 ng HMWK/10^8 platelets, respectively, associated with the material. Alternatively, activated platelets and their supernatant had a mean of 17.3 ng HMWK/10^8 platelets and 17.2 ng HMWK/10^8 platelets, respectively, associated with the aliquots. The increased amount of HMWK made available from the activated platelet specimens must have been derived from the intraplatelet pool of HMWK. The similarity in the decrease in the slopes in the competitive inhibition curves and the calculated amount of available platelet HMWK between the activated platelets and their supernatant indicated that the amount of platelet HMWK expressed on the external platelet membrane after platelet activation is similar to the amount of platelet HMWK secreted from activated platelets.

It is possible that the antibody consumption by thrombin-activated normal platelets was not specifically due to expressed platelet HMWK, but rather due to alterations on the platelet surface as result of thrombin stimulation. In order to evaluate this possibility, the competitive inhibition curves produced by antibody adsorbed by unstimulated and thrombin-activated total kininogen-deficient platelets,[5] as well as the activated deficient platelet supernatant, were compared (inset, Fig 4). Adsorption of the anti-HMWK antisera by unstimulated total kininogen-deficient platelets, thrombin-activated total kininogen-deficient platelets, and activated deficient platelet supernatant produced competitive inhibition curves with calculated slopes of 0.71, 0.78, and 0.77, respectively. These slopes were similar to the competitive inhibition curve produced by unadsorbed antisera and, when corrected for the number of platelets in the experiment, gave values for available HMWK <1 ng HMWK/10^8 platelets—the lower limit of sensitivity of the assay. These data indicated that the consumption of the anti-HMWK antibody by activated platelets was specific for the surface expression of platelet HMWK.

Platelet proteolysis of purified ^{125}I-HMWK. Studies were initiated to determine if platelet enzymes have any effect on the structure of purified HMWK. Initial studies were performed on supernatants of frozen and thawed platelets in the presence or absence of DFP (5 mmol/l) and leupeptin (0.5 mmol/L). Platelets were lysed by freezing and thawing as described in the Materials and Methods Section. As shown in Fig 5 (right), uninhibited supernatants of platelet lysates (2.1×10^{10} platelets per milliliter) produced increasing extent of proteolysis of exogenous purified ^{125}I-HMWK as a function of the lysate concentration. The initial proteolysis of the untreated samples, seen best with platelet lysate concentrations of 10% and 20%, resulted in the appearance of an intermediate mol wt 100,000 band, accentuation of a mol wt 75,000 band which existed in trace amounts in the starting material, a thick mol wt 62,000 band, and the appearance of a mol wt 47,000 band along with small cleavage products at the dye front. As the concentration of platelet lysate increased (40% to 100%), the starting mol wt 120,000 band and intermediate mol wt 100,000 band disappeared, the thick mol wt 62,000 band increased in intensity, and a few new bands, below mol wt 47,000, appeared. Combined treatment of supernatants of platelet lysates with 5 mmol/L of DFP and 0.5 mmol/L of leupeptin prevented all proteolysis (Fig 5, left).

Nature of the Platelet Protease(s) That Cleaves ^{125}I-HMWK. The nature of the platelet protease(s) that produced cleavage of ^{125}I-HMWK was studied further. Platelet cytosol made from 1.0×10^{10} platelets per milliliter was prepared and, in individual aliquots, was pretreated with a wide variety of serine and cysteine protease inhibitors (Fig 6). The addition of leupeptin (0.5 mmol/L), iodoacetamide (0.5 mmol/L), *N*-ethylmaleimide (0.5 mmol/L) and EDTA (10 mmol/L) prevented the proteolysis of ^{125}I-HMWK into a mol wt 100,000 band as well as multiple bands of lower mol wt by platelet cytosol. However, pretreatment of platelet cytosol with DFP (5 mmol/L), soybean trypsin inhibitor (100 μg/mL), benzaminidine (5 mmol/L), or aprotinin (1,000 KIU), did not. This finding indicated that a divalent cation dependent cysteine protease(s) [Calpain(s)] from the platelet cytosol was mostly responsible for cleavage of exogenous ^{125}I-HMWK into a mol wt 100,000 band along with the appearance of other lower mol wt bands.

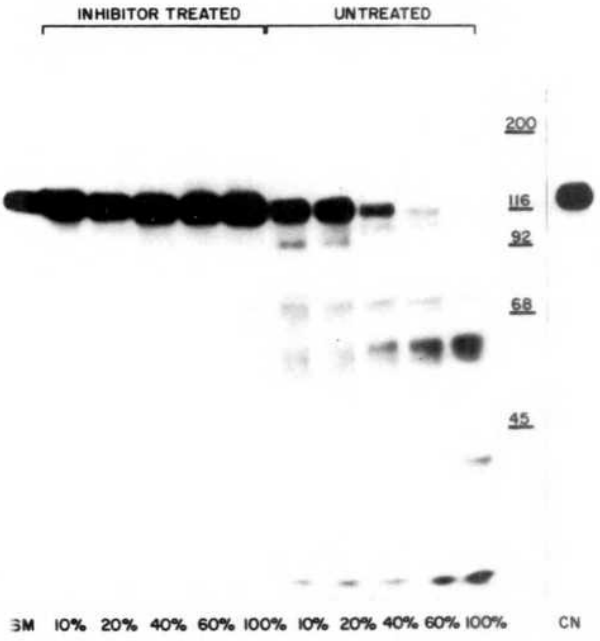

Fig 5. Platelet proteolysis of purified ^{125}I-HMWK. Platelets were washed and resuspended in 3 mL of wash buffer and deionized water (2:1) and were lysed by freezing and in thawing; the supernatant from 2.1×10^{10} platelets per milliliter was divided in half. One-half of the supernatant was incubated for 30 minutes at room temperature in the presence or absence of DFP (5 mmol/L) plus leupeptin (0.5 mmol/L). After incubation, five 100-μl samples were made of both the inhibitor-treated and untreated samples consisting of 10%, 20%, 40%, 60%, or 100% of platelet lysate in (TBS) 0.1 mol/L of Tris, 0.15 mol/L of NaCl, pH 7.4. At the conclusion of the incubation, ^{125}I-HMWK (1.25 nmol/L) (specific radioactivity 3.3 μCi/μg) was added to each aliquot, and the mixture was incubated for ten minutes at 37 °C. At the conclusion, all samples were frozen at −70 °C. For the gel, 25 μL from each aliquot was reduced with 2% β-mercaptoethanol and applied directly to a 7.5% polyacrylamide gel in sodium dodecyl sulfate for electrophoresis; after drying, autoradiography was performed. SM represents 3.75 ng of the ^{125}I-HMWK starting material applied directly to the gel. CN represents an incubation in which purified ^{125}I-HMWK (1.25 nmol/L) was added to platelet buffer and handled identically to the platelet samples. The number to the right of the gel represents mol wt standards.

Activation of HMWK by a platelet protease. Although a platelet divalent cation dependent cysteine protease was responsible for cleavage of HMWK, the significance of this cleavage was unclear. To study whether changes in the HMWK molecule altered its activity, purified HMWK in a final concentration of 3 U/mL (12.7 U/mg) was added to platelet supernatants pretreated with leupeptin or left untreated (Table 1). As seen in Table 1, platelet lysate alone

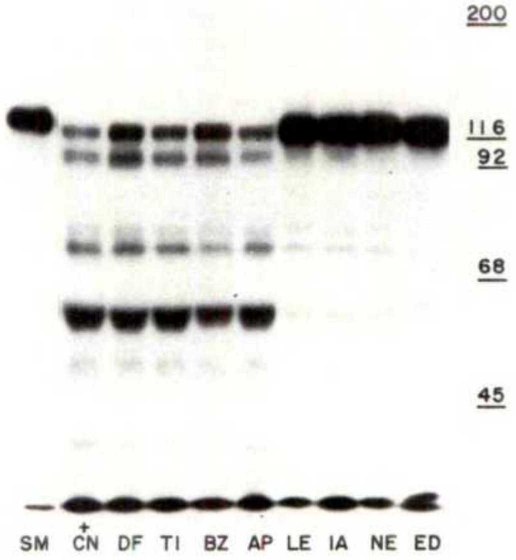

Fig 6. Effect of protease inhibitors on the appearance of the 100,000 mol wt cleavage product of ^{125}I-HMWK. A 100,000 g cytosol of platelets (1.0 × 10^{10} platelets per milliliter) were treated with various serine and cysteine protease inhibitors for ten minutes at 37 °C. Thirty nanograms of ^{125}I-HMWK (5 nmol/L with a specific radioactivity, 3 μCi/μg) was added to an 80% mixture of inhibitor-treated platelet cytosol and incubated for one hour at 37 °C. SM, ^{125}I-HMWK incubated in buffer; (+)CN, ^{125}I-HMWK added to a mixture which consisted of 80% platelet cytosol in 0.1 mol/L of Tris, 0.15 mol/L of NaCl, pH 7.4 (TBS). DF, ^{125}I-HMWK added to platelet cytosol pretreated with 5 mmol/L of diisopropylfluorophosphate (DFP); TI, 4.76 nmol/L of soybean trypsin inhibitor; BZ, 5 mmol/L of benzamidine; AP, 1,000 KIU of aprotinin; LE, 0.5 mmol/L of leupeptin; IA, 0.5 mmol/L of iodoacetamide; NE, 0.5 mmol/L of *N*-ethylmaleimide; and ED, 10 mmol/L of EDTA. Polyacrylamide gel electrophoresis in sodium dodecyl sulfate and auto radiography were performed as described in Fig 5. The numbers to the right of the gel represent mol wt standards.

contributed little coagulant activity (<0.1 U/mL) and leupeptin in the concentration used (0.5 mmol/L) did not inhibit the coagulant assay, since leupeptin-treated buffer (2.5 U/mL) had similar coagulant activity to untreated buffer (2.9 U/mL). However, when comparing the coagulant activity of the exogenous HMWK in the leupeptin-treated (3.1 U/mL) *v* the untreated specimen (22 U/mL, 93.6 U/mg) after a two-hour incubation, HMWK exposed to the untreated platelet supernatant exhibited sevenfold increased specific activity. Because the purified HMWK was added in a final concentration of about 3 U/mL, the increased activity measured in the untreated specimen must have been due to "activation" of the exogenous HMWK by a leupeptin-sensitive protease. In separate experiments not shown in Table 1, leupeptin in a concentration of 0.1 mmol/L and iodoacetamide (0.5 mmol/L) also inhibited the increase in exogenous HMWK coagulant activity by platelet cytosols.

Table 1. Platelet Activation of HMWK

Material*	(+) Leupeptin† (U/mL)	(−) Leupeptin (U/mL)
Platelet lysate + HMWK*‡	3.1	22
Platelet lysate alone‡	<0.1	<0.1
Buffer + HMWK‡	2.5	2.9

*Supernatants from lysed platelets per milliliter (6.31 × 10^9) were used to make an 85% mixture with buffer (0.1 mol/L of Tris, 0.15 mol/L of NaCl, pH 7.4) and/or purified HMWK [stock 30 U/mL (20 μmol/L) or 12.7 U/mg]. Purified HMWK was diluted 1:10 in the reaction mixture. Samples were incubated for two hours at 37 °C.

†Leupeptin-treated lysate was prepared by the addition of leupeptin (0.5 mmol/L) ten minutes prior to the addition of purified HMWK.

‡Samples for HMWK coagulant assay were diluted 1:10 prior to testing. Data presented represent the mean results of three experiments.

Time course of activation of HMWK by a platelet protease. The activation of exogenous purified HMWK by platelet cytosol was studied in kinetic experiments. A 100,000 g cytosol of lysed platelets (8 × 10^9 platelets per milliliter) containing 1 mmol/L of EDTA was prepared in the presence or absence of leupeptin (Fig 7). After the addition of calcium (2.5 mmol/L), the coagulant activity of exogenous purified HMWK (final concentration of 2 U/mL or 12.5 U/mg before the addition of calcium) in the untreated platelet cytosol rose rapidly to 70 U/mL or 437 U/mg within ten minutes. This result indicated a 35-fold increase in coagulant activity. At longer incubations, the activity decreased, but at two hours the coagulant activity was 20 U/mL, ten times the original activity. No significant increase (2 to 4 U/mL) in the coagulant activity of exogenous HMWK added to the leupeptin-treated platelet cytosol was noted during the six-hour incubation.

Additional studies were performed to determine if bradykinin was released simultaneously with the cleavage of ^{125}I-HMWK and the increase in exogenous HMWK coagu-

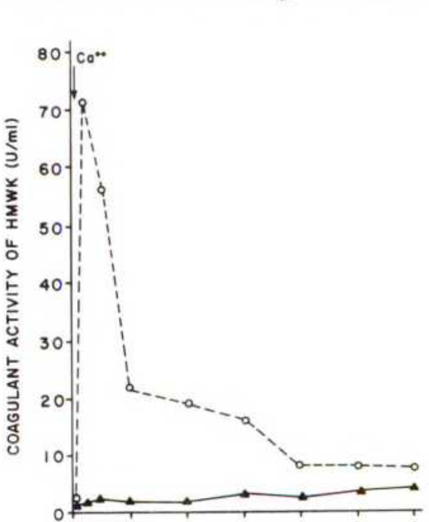

Fig 7. Time course of activation of HMWK coagulant activity by a platelet protease. A 100,000 g cytosol of platelets from 8 × 10^9 platelets per milliliter containing EDTA (1 mmol/L) was pretreated with leupeptin (0.5 mmol/L) (▲—▲) or left untreated (○---○). After the addition of purified HMWK [final concentration 2 U/mL (1.33 μmol/L)] into a mixture which consisted of 90% platelet cytosol in (0.1 mol/L of Tris, 0.15 mol/L of NaCl, pH 7.4) (TBS), the activation of HMWK was initiated by the addition of $CaCl_2$ (2.5 mmol/L). Samples were removed at 0 minutes, 10 minutes, 30 minutes, and at hourly intervals to determine the coagulant activity of HMWK. All incubations were performed at 37 °C.

lant activity. Under conditions similar to the coagulant activity studies of exogenous HMWK added to platelet cytosol, no bradykinin release was measurable. Because the possible amount of bradykinin released from the added HMWK could have been as much as 100-fold greater than the sensitivity of the radioimmunoassay to measure bradykinin, additional studies were performed to determine whether platelet cytosol contained an enzyme(s) that degraded bradykinin. It was found that platelet cytosol contained a DFP-sensitive enzyme that degraded exogenous bradykinin. Less than 10% of added bradykinin could be recovered from platelet cytosol, indicating that any released bradykinin by a calpain cleavage of HMWK in platelet cytosol would be rapidly proteolyzed.

DISCUSSION

The studies presented here indicate two potential pathways, perhaps interrelated, by which the interaction of HMWK with platelets may assume significance in the proteolytic reactions involved in contact phase activation. Platelet HMWK is expressed on the activated platelet surface and a platelet calcium-dependent cysteine protease(s) [Calpain(s)] is responsible for cleavage and increased coagulant activity of the HMWK molecule. Because platelet HMWK has been shown to be secreted from metabolically active platelets,[5] it was not surprising that the largest amount of the protein was found in the granule fractions enriched with α-granules in the unstimulated platelet (Figs 1 and 2). By radiolabeled HMWK tracer studies, the amount of HMWK found in the F_2 granule fraction must have been derived from the platelet granules themselves, since only 0.3% of a soluble HMWK tracer was attached to or trapped in the granule fraction. Furthermore, the amount of HMWK localized to the C/D α granule fraction must also have been derived from the platelet granules, since only 0.072% of the total soluble [^{125}I]HMWK was found to be associated with this fraction. The subcellular fractionation studies were confirmed by a study on the total amount of platelet HMWK in platelets from a patient with the gray platelet syndrome.[7] These platelets contained 16 ng/10^8 platelet HMWK, which is 28% of normal.

The finding that platelet HMWK is expressed on the external membrane of activated platelets (Fig 4) suggests one mechanism whereby a platelet form of a protein, which exists in the platelet in smaller quantities than in plasma, could be important. The expression of the platelet form of the protein on the activated platelet surface may be the means by which higher local concentrations of the protein may be achieved on the platelet surface than in plasma.[29] The validity of the modified CELISA as a quantitative indirect antibody consumption assay used in this study to determine the amount of membrane-expressed platelet HMWK is shown by comparison of the present results with our previously reported data.[5] In our previous study, we directly determined the amount of HMWK in supernatants of washed platelets to contain 2.8 ng HMWK/10^8 platelets.[5] In the present study, using the curve in Fig 3, we calculated that the supernatants of washed unstimulated platelets contain 4.2 ng HMWK/10^8 platelets. In addition, in the previous study, we estimated that washed platelets themselves have about 5 ng HMWK/10^8 platelets associated with the platelet suspension. In the present experiments, we estimate that washed platelet suspensions contain 4.9 ng HMWK/10^8 platelets. The similarity between these quantitative studies indicate that assessments as to the amount of platelet HMWK expressed on the activated platelet surface are valid.

In the present experiments, it was estimated that an amount of the total platelet HMWK equal to that which was secreted also was expressed on the activated platelet surface (Fig 4). This assessment is derived from the finding that activated platelets and their supernatant adsorbed similar amounts of the antibody to HMWK, as indicated by the similar decrease in the slopes of the competitive inhibition curves in Fig 4. Comparing the calculated slopes of the competitive inhibition curves produced by activated platelets and their supernatants in four experiments with the slope of the competitive curves produced by the antisera adsorbed with variable concentrations of purified HMWK (Fig 3), the amount of platelet HMWK expressed on the platelet surface and simultaneously secreted from platelets was ~17 ng/10^8 platelets. Comparing this value with the normal value of total platelet HMWK (60 ng/10^8 platelets),[5] ~28% of the total amount of platelet HMWK becomes secreted and independently expressed on the membrane of the activated platelet. This value for the amount of secreted platelet HMWK is lower than that (63%) which we previously reported for thrombin-activated platelets.[5] It is possible that the difference resulted from the threefold greater concentration of thrombin used for induction of the secretion reaction in the latter experiments. The presence of HMWK on the platelet surface suggests that the platelet, through the expression of its HMWK, may be an in vivo negatively charged surface for the regulation of the contact proteolytic system. Further studies are needed to determine if membrane-expressed platelet HMWK exists there in a high local density.

The finding that a platelet protease(s) cleaves HMWK (Figs 5 and 6) is not surprising, since calcium-requiring platelet proteases have been demonstrated to cleave other hemostatic cofactors: factor V, platelet fibrinogen, and von Willebrand factor.[30-32] In these studies with HMWK, a 100,000 mol wt cleavage product of HMWK along with lower mol wt bands are recognized (Figs 5 and 6). Because the cleavage of ^{125}I-HMWK consistently resulted in a 100,000 mol wt band and was inhibited by agents known to inhibit platelet calpain(s), but was unaffected by several other serine protease inhibitors that do not inhibit platelet calpain (Fig 6), it is likely that the cleavage of ^{125}I-HMWK observed in this study is a direct effect of calpain(s) and is not mediated through a secondary protease that is activated by calpain. Previous studies with purified proteins and in plasma indicated that kallikrein cleaves HMWK into heavy (64,000 mol wt) and light (46,000 mol wt) chains with an intermediate (56,000 mol wt) light chain.[4,33] Similar cleavage of HMWK occurs with factor XIa, although the initial cleavage of HMWK results in a 74,000 mol wt band.[34] The finding that a platelet cysteine protease(s) (Fig 6) is responsible for an additional 100,000 mol wt cleavage product of

HMWK would explain why this cleavage intermediate has not been recognized with purified plasma enzymes or in plasma when activated by a surface. The extent of proteolysis of ^{125}I-HMWK seen in these studies was probably dependent upon the amount of platelets that was used to prepare the cytosol. When there was a high concentration of platelet enzymes (Fig 5), both the 120,000 mol wt band and the 100,000 mol wt band of ^{125}I-HMWK were completely proteolyzed.

The finding that platelet calpain(s) can increase the specific coagulant activity of HMWK (Table 1, Fig 7) suggests that HMWK may be an important substrate for platelet calpains. The mechanism whereby platelet calpains increase the coagulant activity of HMWK is presently unknown. Because multiple bands are formed by platelet calpain cleavage of ^{125}I-HMWK, it is not clear which cleavage product is responsible for the measured increased specific coagulant activity of HMWK. In a previous study,[4] our group showed that kallikrein-cleaved HMWK had increased surface binding activity, and the amount of HMWK that adsorbed to an artifical surface was directly related to the expression of HMWK coagulant activity. That study suggests that proteolysis of HMWK, which exists as a procofactor, allows for increased surface-mediated activity. In that previous study,[4] it was not possible to make a direct measurement of the specific coagulant activity of the kallikrein-cleaved HMWK such as was performed in the present investigation since prekallikrein is in the substrate plasma of the coagulant assay and when activated on a surface must produce similar cleavages during the one-stage assay procedure. However, both studies suggest that proteolysis of the HMWK can augment its activity. The present investigation supports the hypothesis that HMWK exists as a procofactor. Additional studies with purified platelet calpain and HMWK or its light chains are needed to determine whether the 100,000 mol wt band or some other cleavage product appearing at the same time is responsible for the increased HMWK coagulant activity. Furthermore, since platelet cytosols contain an enzyme(s) that degrades bradykinin, neither was it possible to determine whether platelet calpain(s) releases bradykinin. Further studies are needed with purified platelet calcium-activated cysteine protease(s) on purified intact HMWK to confirm whether this enzyme(s) releases bradykinin.

The interaction between HMWK and platelet calpains may be more than fortuitous. The recognition that HMWK is a substrate for platelet calpain[35] has been corroborated with recent studies. Evidence by Ohkubo et al[36] and Muller-Esterl et al[37] indicate that α-2-thiol proteinase inhibitor—a major plasma proteinase inhibitor of cysteine proteases[38]—is identical to plasma low mol wt kininogen. Because the synthesis of the plasma kininogens is controlled by one gene,[39] the heavy chain of HMWK is identical to the heavy chain of low mol wt kininogen. HMWK, which differs from low mol wt kininogen by the presence of a light chain that contains its coagulant activity,[39,40] may be both a substrate and inhibitor of platelet calpains. Because it is well recognized that protease inhibitors are also substrates,[41] further studies are required to determine if purified HMWK inhibits purified platelet calpain.

Several laboratories have reported the presence of a calcium-dependent platelet protease(s)[42-46] which cleaves platelet membrane proteins,[43-46] alters endothelial prostaglandin production,[42] cleaves factor V,[30] fibrinogen,[31] and von Willebrand factor.[32] At least two calcium-dependent cysteine proteases are ubiquitously distributed in tissues, Calpain I and Calpain II, which differ in their requirement for activation by calcium; Calpain I requires μmol/L concentrations of calcium and Calpain II requires mmol/L concentrations.[47-49] To date, these proteases have been purified only from the cytosol fraction of the tissue from which it is derived.[42,48,49] How these calpains become available to alter their substrates, which are either on the platelet surface or contained within platelet granules, is unknown. However, these substrates may become altered by platelet calpains when platelets are disrupted by mechanical injury or complement-mediated cytolysis. This later notion would be consistent with our current hypothesis on the importance of HMWK. Because a deficiency of HMWK is not associated with any specific disease state, but the protein becomes altered to participate in the consequences of many disease states,[50] HMWK should be considered as a pathophysiologic mediator. HMWK in plasma or platelets could serve to inhibit platelet calpain(s) directly by its heavy chain and to neutralize the consequences of calpain's action indirectly by the formation of an activated cofactor form. In conclusion, these studies indicate that activated platelets express platelet HMWK on their surface that may be available to promote contact phase proteolysis on or at the platelet surface, and that platelets themselves contain a calpain protease(s) that can cleave HMWK and increase its coagulant activity and that might accelerate contact phase activation.

ACKNOWLEDGMENT

We would like to express our appreciation to Dr Linda Knight and Monica Kollman for their aid in radiolabeling; Carol Silverman, Gail Pakstis, Sandra Wadsworth, and Anthony Farber for additional technical assistance; Dr Leon Salganicoff for his advice on platelet subcellular fractionation; and Pat Pileggi for her excellent secretarial skills.

Platelet-Derived Growth Factor Does Not Stimulate Prostacyclin Synthesis by Cultured Endothelial Cells

By Karleen S. Callahan, Anna Schorer, and John M. Harlan

We examined the effect of highly purified platelet-derived growth factor (PDGF) on prostacyclin (PGI_2) release by cultured human umbilical vein and bovine aortic endothelial cells. PDGF tested at concentrations equal to or exceeding those observed in serum did not increase endothelial cell PGI_2 synthesis as measured by radioimmunoassay of its metabolite, 6-keto-$PGF_{1\alpha}$. In contrast, cells incubated with 20% human whole blood serum (WBS) demonstrated significantly increased PGI_2 production (fivefold stimulation). Addition of anti-PDGF antibody to the 20% WBS did not attenuate the increased synthesis of PGI_2. Incubation with 20% plasma-derived serum (PDS) that was deficient in PDGF produced stimulation of PGI_2 release similar to 20% WBS. These results demonstrate that PDGF does not cause increased PGI_2 synthesis in cultured human endothelial cells of human or bovine origin, and further suggest that the stimulation observed with serum is not due to a platelet-release product.

THE INTERACTION of platelets and endothelium with respect to thromboxane A_2 and prostacyclin (PGI_2) synthesis by these respective cell types has been extensively investigated. Although platelet-derived endoperoxides may supply substrate for endothelial prostaglandin formation,[1] the effects of platelet-derived proteins on endothelial cell prostanoid synthesis are not well defined.[2-6] Platelet activation by various physiologic stimuli results in the release of platelet α granule constituents including purified platelet-derived growth factor (PDGF), a potent mitogen which may contribute to wound repair following injury.[7-9] PGI_2, a major arachidonic acid metabolite produced by endothelium, is a potent vasodilator and inhibitor of platelet aggregation and release.[10] Previous investigations have reported increased prostaglandin synthesis in cultured cell systems including bovine aortic endothelial cells following incubation with PDGF,[11,12] and it was postulated that increased vascular PGI_2 production due to PDGF might act as a negative feedback mechanism for limiting platelet aggregation at sites of vascular injury.[4] The current study was designed to investigate this hypothesis by examining the effects of highly purified human PDGF,[13] as well as specific PDGF antibody, on PGI_2 synthesis in cultured human umbilical vein endothelial cells.

MATERIALS AND METHODS

Cell culture. Human umbilical vein and bovine aortic endothelial cells were isolated by collagenase treatment of vessels as previously described.[14] The human endothelial cells were maintained in 20% fetal calf serum (FCS), and the bovine cells were maintained in 10% FCS (Hyclone Laboratory, Logan, Utah) in either RPMI 1640 (human) or Waymouth's (bovine) medium (Grand Island Biologic Company, Grand Island, NY). Endothelial cells were passaged following trypsinization and plated at confluent density in 16-mm diameter wells (Costar, Cambridge, Mass). The human umbilical vein endothelial cells were used in first passage, and the bovine aortic endothelial cells were used in eighth passage. Bovine aortic smooth muscle cells at fifth passage were provided by Dr Stephen Schwartz, University of Washington, Seattle. Human foreskin fibroblasts were prepared as previously described[15] and were generously provided by Dr Russell Ross, University of Washington, Seattle.

Radioimmunoassay of endothelial cell 6-keto $PGF_{1\alpha}$ release. Prior to treatment, the monolayers were gently washed twice with 2.0 mL of serumless Neuman-Tytell medium which contains 0.2% lactalbumin (Grand Island). The wash medium was decanted and replaced with 0.5 mL of Neuman-Tytell medium containing control or test agents for an overnight incubation (24 hours) at 37 °C in 5% CO_2, 95% air. At the end of 24 hours, an aliquot of cell-free supernatant medium was removed from each well, placed into a polypropylene tube, and immediately frozen in a methanol-dry ice bath for storage at −20 °C until assayed. In selected experiments, the endothelial monolayers were gently washed again, the supernatant medium was decanted, and 0.5 mL of serumless Neuman-Tytell medium with or without purified human α-thrombin or A23187 was added for an additional 30-minute incubation. At the end of this time, the cell-free supernatant medium was removed and treated as above for later radioimmunoassay. Cell counts were performed on replicate wells by electronic particle counter (Particle Data, Inc, Elmhurst, Ill).

Measurement of unextracted, supernatant medium from the endothelial cell cultures for PGI_2 production was determined by radioimmunoassay (RIA) of the stable PGI_2 metabolite using [^{3}H]6-keto-$PGF_{1\alpha}$ (Amersham, Arlington, Ill), authentic 6-keto-$PGF_{1\alpha}$ standard kindly provided by Douglas McCarter and Dr John Pike, The Upjohn Company, Kalamazoo, Mich, and antiserum generously supplied by Dr William B. Campbell, University of Texas Health Science Center at Dallas. This anti-6-keto-$PGF_{1\alpha}$ antiserum cross-reacted <0.9% with PGE_1, PGE_2, $PGF_{1\alpha}$, $PGF_{2\alpha}$, PGD_2, PGA_2, and TxB_2, 3.5% with 6, 15-diketo $PGF_{1\alpha}$, and 70% with 6-keto-PGE_1. The level of sensitivity was 10 pg/300 μL, and assays were run in duplicate and at more than one dilution when necessary. The proteins in the Neuman-Tytell medium did not interfere in the RIA and recovery of exogenous 6-keto-$PGF_{1\alpha}$ added to Neuman-Tytell medium was 106.7% ± 5.8%.

Preparation of whole blood serum (WBS) and plasma-derived serum (PDS). Human WBS was prepared following venipuncture from a single normal donor by allowing the blood to sit at room temperature until clotted (~two hours). The blood was then centrifuged at 2000 g for 20 minutes, and the cell-free serum was collected and passed through a 0.2 μm filter (Millipore, Bedford, Mass) in order to obtain a sterile preparation. The WBS was stored at 4 °C until used. PDS was prepared by collecting normal human blood from several donors into precooled syringes containing 3.5% citrate at a final dilution of 1:10 (vol/vol). The sample was immediately

centrifuged at 2500 g for 20 minutes at 4 °C. The cell-free and platelet-free plasma was recalcified, dialyzed against phosphate-buffered saline (PBS) to remove citrate, centrifuged to remove the clot, and stored at 4 °C.

Radioreceptor assay of PDGF. Levels of PDGF in WBS and PDS were determined by radioreceptor assay using human foreskin fibroblasts and ^{125}I-labeled PDGF as described by Bowen-Pope and Ross.[15] In brief, confluent fibroblast monolayers were put on ice and rinsed with cold PBS containing 0.1% bovine serum albumin (BSA) and 0.5 mmol/L of CaCl, pH 7.4. This binding rinse was aspirated from the cells and replaced with 1.0 mL per well of test solution for a three-hour incubation at 4 °C with constant shaking. Next, the supernatant was removed and replaced with 1.0 mL per well of 25 mmol/L of Hepes buffer, pH 7.4, containing 0.25% BSA and 0.5 ng ^{125}I-PDGF. The fibroblasts were incubated at 4 °C with shaking for one hour, the supernatant was aspirated, and the cells were washed twice with the binding rinse to remove unincorporated ^{125}I-PDGF. Finally, the cells were solubilized with 0.1% Triton X-100 (New England Nuclear, Boston) in water containing 0.1% BSA and were collected for gamma counting. This radioreceptor assay detects levels of >0.1 ng PDGF/1.0 mL.

Reagents. Highly-purified PDGF[13] and goat anti-human PDGF antibody were generously supplied by Dr Elaine Raines and Dr Russell Ross, University of Washington, Seattle. The PDGF preparation was a 500,000-fold purification from serum and consists of four components with mol wts of 27,000 to 31,000 in the nonreduced state using 15% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). PDGF was stored in 10 mmol/L of acetic acid containing 0.25% BSA, which was diluted a 100-fold or more in Neuman-Tytell media for experiments. A comparable volume of this acetic acid solution was added to control cultures. The IgG fraction of goat anti-human PDGF antiserum was prepared by 18% Na_2SO_4 precipitation and diethylaminoethanol (DEAE)-sephacel chromatography. The anti-PDGF IgG (at a concentration of 20 μg/mL) completely inhibits 1 ng/mL purified PDGF or an equivalent amount of PDGF in WBS as determined by mitogenic activity or ability to compete with ^{125}I-PDGF in the radioreceptor assay (E. R., personal communication). Purified human α-thrombin (12,000 U/mg protein) was generously provided by Dr John Fenton II, (Buffalo). A23187 was obtained from Sigma Chemical Company.

Statistical analysis. The results were evaluated by analysis of variance with the Neuman-Keul's multiple comparisons test.

RESULTS

Figure 1 shows the effects of WBS and PDS on endothelial PGI_2 synthesis as measured by RIA of 6-keto-$PGF_{1\alpha}$. Incubation of the human endothelial cell monolayers with 20% human WBS resulted in a significant increase in 6-keto-$PGF_{1\alpha}$ release when compared with incubation in serumless medium alone. Comparable stimulation was observed with WBS prepared from a pool of donors. Addition of the anti-PDGF IgG to 20% WBS did not attenuate the stimulatory effect. Anti-PDGF IgG alone did not increase 6-keto-$PGF_{1\alpha}$ synthesis over that observed with medium alone (data not shown). Addition of 20% PDS, however, caused a significant increase over medium alone (Fig 1). There was no further stimulation over that observed with PDS alone when PDGF was added to 20% PDS (data not shown). The concentration of PDGF in WBS was 17.0 ng/mL, 1.3 ng/mL in WBS containing anti-PDGF IgG, and <0.1 ng/mL in PDS.

In contrast to the results obtained with WBS or PDS, a 24-hour incubation of human endothelial cells with purified PDGF (10 to 100 ng/mL) did not result in stimulation of 6-keto-$PGF_{1\alpha}$ production (Fig 2). The reported values of PDGF in human whole blood serum are 17.5 ng/mL by radioreceptor assay[16] or 50.0 ng/mL by radioimmunoassay.[17]

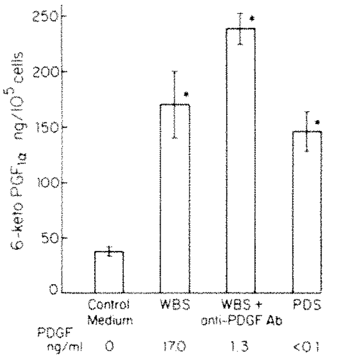

Fig 1. Effect of whole blood serum (WBS) and plasma-derived serum (PDS) on 6-keto-$PGF_{1\alpha}$ release. Human umbilical vein endothelial cell monolayers were incubated with medium alone (n = 16), medium containing 20% WBS (n = 12), 20% WBS with anti-platelet-derived growth factor (PDGF) antibody (Ab) (n = 8), or 20% PDS (n = 8). Aliquots of supernatant medium were removed after 24-hour incubation for determination of 6-keto-$PGF_{1\alpha}$ levels by RIA. Values represent means ± 1 SE from quadruplicate wells in two to four individual experiments (* $P < .01$). The levels of PDGF in the serum preparations were determined by radioreceptor assay.

We also examined the effects of platelet products on subsequent thrombin-induced PGI_2 synthesis as shown in Fig 3. The cells were incubated for 24 hours with various treatments, washed once, and incubated with fresh medium with or without α-thrombin for 30 minutes. α-Thrombin induced a marked increase in 6-keto-$PGF_{1\alpha}$ synthesis in cells preincubated in medium alone and in cells preincubated with either PDGF or WBS. In contrast, monolayers previously incubated with α-thrombin were refractory to subsequent stimulation by α-thrombin, as reported by others.[18]

Because the previous report of PDGF-stimulated endothelial cell PGI_2 release used bovine aortic endothelial cells,[4] we

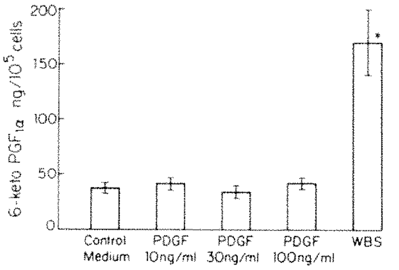

Fig 2. Effect of platelet-derived growth factor (PDGF) on 6-keto-$PGF_{1\alpha}$ release. Human umbilical vein endothelial cell monolayers were incubated with medium alone (n = 16), medium containing PDGF 10 ng/mL (n = 16), PDGF 30 ng/mL (n = 8), PDGF 100 ng/mL (n = 4), or medium containing 20% WBS (n = 8). Aliquots of supernatant medium were removed after 24-hour incubation for determination of 6-keto-$PGF_{1\alpha}$ levels by RIA. Values represent means ± 1 SE from quadruplicate wells in one to four experiments (* $P < .01$).

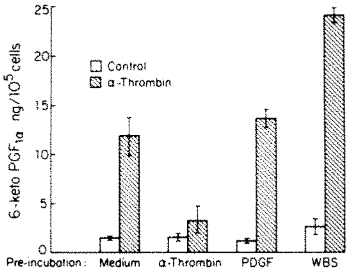

Fig 3. Effect of platelet-derived proteins on thrombin-stimulated 6-keto-PGF$_{1\alpha}$ release. Human umbilical vein endothelial monolayers were incubated for 24 hours with medium alone, medium containing 8 U/mL α-thrombin, 10 ng/mL PDGF, or 20% WBS. The monolayers were then washed and incubated with medium alone or medium containing α-thrombin (8 U/mL). Aliquots of supernatant medium were removed after 30-minute incubation for determination of 6-keto-PGF$_{1\alpha}$ levels by radioimmunoassay. Values represent means ± 1 SE from quadruplicate wells in two experiments.

repeated similar experiments using our PDGF preparation and bovine aortic endothelial cells (Table 1). Although PGI$_2$ synthesis in these multiple passages of bovine endothelial cells was considerably less than in the human endothelial cells, addition of PDGF (10 to 100 ng/mL) did not increase 6-keto-PDF$_{1\alpha}$ release when compared with serumless medium alone. These same bovine cells were able to respond to subsequent stimulation using calcium ionophore A23187 or 20% WBS (data not shown).

Finally, we examined the effect of PDGF on PGI$_2$ synthesis in another vessel wall cell type. In contrast to human or bovine endothelial cells, bovine aortic smooth muscle cells demonstrated increased 6-keto-PGF$_{1\alpha}$ synthesis following incubation with PDGF (Table 1). PDGF caused a greater than tenfold increase in 6-keto-PGF$_{1\alpha}$ release in smooth muscle cells. In addition, 6-keto-PGF$_{1\alpha}$ synthesis was significantly increased in smooth muscle cells exposed to 20% WBS when compared with those incubated in 20% PDS. Although addition of anti-PDGF IgG to WBS resulted in decreased PGI$_2$ synthesis as compared with WBS alone, the amount released was still significantly higher than with medium alone (Table 1).

Table 1. Effect of PDGF on Bovine Vessel Wall Cell PGI$_2$ Release

		6-keto-PGF$_{1\alpha}$ ng/10^5 Cells*
Addition to bovine aortic endothelial cells		
Control	(3)	1.34 ± 0.22
PDGF		
10 ng/mL	(3)	0.80 ± 0.06
50 ng/mL	(3)	0.96 ± 0.06
100 ng/mL	(3)	0.99 ± 0.13
Addition to bovine aortic smooth muscle cells		
Control	(4)	0.32 ± 0.04
PDGF		
10 ng/mL	(4)	4.02 ± 0.14*
20% WBS	(4)	18.84 ± 0.68*
20% PDS	(4)	5.14 ± 0.50*
20% WBS + anti-PDGF Ab	(4)	14.24 ± 0.88*

PDGF, platelet-derived growth factor; WBS, whole blood serum, PDS, plasma-derived serum.

6-Keto-PGF$_{1\alpha}$ levels in supernatant medium were determined by RIA after a 24-hour incubation. Values represent means ± 1 SE of (n) replicate wells.

DISCUSSION

Previous investigations have demonstrated that PGI$_2$ production by endothelial cells is stimulated by unidentified factor(s) present in normal plasma and serum.[19-23] Coughlin et al,[4] using cultured bovine aortic endothelial cells, demonstrated that serum prepared from platelet-rich plasma produced a greater increase in PGI$_2$ release than did serum prepared from platelet-poor plasma. The serum factor described in that report was similar to PDGF in being heat-stable and nondialyzable; they also found that addition of partially purified PDGF resulted in significant enhancement of PGI$_2$ synthesis within 24 hours. These investigators suggested that PDGF or other products released by activated platelets might provide feedback inhibition of further platelet aggregation by stimulating endothelial PGI$_2$ production.[5]

We did not observe an increase in PGI$_2$ production when cultured human umbilical vein or bovine aortic endothelial cells were incubated with purified PDGF at concentrations equal to or exceeding normal serum levels (Fig 2 and Table 1). Although incubation with WBS significantly increased PGI$_2$ synthesis, PDS that lacked PDGF produced a similar increase. Furthermore, addition of specific anti-PDGF IgG to the WBS did not attenuate the enhanced PGI$_2$ generation (Fig 1). These observations demonstrate that PDGF is not the stimulating factor in serum responsible for enhanced PGI$_2$ synthesis by cultured endothelial cells.

We also found that prior incubation of the endothelial cells with either PDGF or WBS did not attenuate subsequent stimulation of PGI$_2$ induced by α-thrombin (Fig 3). These observations suggest that platelet-derived products do not down regulate endothelial PGI$_2$ synthesis as has been reported for β-thromboglobulin.[2] PGI$_2$ synthesis by bovine aortic smooth muscle cells was stimulated by purified PDGF, and 20% WBS resulted in greater production of PGI$_2$ than did 20% PDS. In addition, PGI$_2$ production was reduced by the addition of anti-PDGF IgG to WBS. Thus, as previously reported by Coughlin et al,[5] smooth muscle cell PGI$_2$ synthesis is sensitive to platelet-derived products, including PDGF. In all of these studies, it should be noted that WBS and PDS differ in more than platelet release products. Products of leukocytes activated during clotting ex vivo could contribute to the PGI$_2$ stimulatory activity of WBS.

Although our results on endothelial cell response to PDGF differ from those of Coughlin et al,[4] they are similar to those of Poggi and co-workers.[6] These latter investigators examined cultured bovine aortic endothelial cells and reported that partially purified PDGF had an insignificant effect on PGI$_2$ synthesis at 24 hours (140.7% of control). Both of these earlier investigations[4,6] utilized partially purified PDGF prepared according to the method of Antoniades et al,[24] whereas the present study used more highly purified PDGF prepared according to the method of Raines and Ross.[12] Consequently, discrepancies among the studies may be due in part to differences in the PDGF preparations and the possibility of a contaminating serum factor in the earlier studies. Our preparation of PDGF was active as a mitogenic factor in fibroblasts and did stimulate PGI_2 production by cultured smooth muscle cells.

The fact that cultured human umbilical vein and bovine aortic endothelium lack PDGF receptors[25,26] would argue against PDGF-mediated effects on PGI_2 release from these cells although it is possible that PDGF could act by receptor-independent mechanisms. For example, although only native PDGF binds to its receptor and stimulates mitogenesis,[27] both native and reduced PDGF stimulate leukocyte chemotaxis.[28] This observation suggests that receptor binding may not be essential for all cell responses to PDGF.

In conclusion, purified PDGF did not stimulate PGI_2 production in cultured endothelial cells of either human or bovine origin, and an anti-PDGF antiserum did not inhibit PGI_2 generation induced by WBS. Plasma-derived serum with an undetectable level of PDGF also caused significant enhancement of endothelial PGI_2 synthesis, providing further evidence that PDGF is not responsible for the stimulatory effect of human serum on endothelial cell PGI_2 synthesis.

Clinical and Biologic Features Predict A Poor Prognosis in Acute Lymphoid Leukemias in Infants: A Pediatric Oncology Group Study

By W. Crist, J. Pullen, J. Boyett, J. Falletta, J. van Eys, M. Borowitz, J. Jackson, B. Dowell, L. Frankel,
F. Quddus, A. Ragab, and T. Vietti

Analysis of remission induction rates for 1,117 children 18 months to 10 years of age (group 1) and 90 infants <18 months of age (group 2) with acute lymphoid leukemia (ALL) and of duration of continuous complete remission (CCR) for 454 in group 1 and 33 in group 2 revealed that infants fared significantly worse in both measures of outcome ($P = .03$ and $P < .0001$). To examine potential reasons for the poor prognosis of affected infants, clinical and biologic features of their ALL were compared. Infants had higher WBC counts ($P < .001$), a higher incidence of massive splenomegaly ($P < .001$), massive hepatomegaly ($P < .001$), more central nervous system (CNS) disease at diagnosis ($P < .01$), and lower platelet counts ($P < .001$). Also, their blasts were less often PAS$^+$ ($P = .02$). The incidence of non(T, B, pre-B), T and pre-B immunophenotypes of ALL did not differ significantly between the two groups. However, in patients with non(T, B, pre-B) ALL, the majority (51%) of infants had common ALL antigen (CALLA)-negative blasts, as compared with only 7% in group 1 ($P < .001$). Furthermore, infants with non(T, B, pre-B) cell ALL who were <12 months of age were almost always CALLA$^-$ (18 of 21). The blasts of children from both groups usually expressed Ia-like antigens. These data illustrate that infants with ALL have extensive and bulky disease more often than do older children and are more often affected with a prognostically unfavorable phenotype of acute leukemia (AL) which expresses Ia-like antigens but is more often PAS$^-$ and CALLA$^-$. We believe that these clinical and biological differences predict and explain in part the observed poor response to treatment of infants with ALL.

© 1986 by Grune & Stratton, Inc.

THE PROGNOSIS of children with acute lymphoid leukemia (ALL) has improved remarkably during the last decade. Presently, >50% of newly diagnosed children may be expected to survive. However, many children continue to fail treatment and eventually succumb to their disease. The ability to predict which children with ALL have a high probability of treatment failure has recently become possible through the definition of certain prognostic factors that may be determined at the time of diagnosis. These include such clinical or biologic factors as the level of the white blood cell (WBC) count,[1-3] age,[3] presence of organomegaly,[1,2,4-6] gender,[1,2,5,7] tumor cell ploidy and/or karyotype,[8,9] platelet count,[1,10] presence of a mediastinal mass,[2,4,11,12] race,[10,13,14] cell morphology,[15-19] immunophenotype,[3,12,20-24] rapidity of achieving bone marrow remission,[15] the presence of central nervous system (CNS) leukemia at the time of diagnosis,[2,4] glucocorticoid receptor levels in blasts,[25] and blast PAS positivity.[26] Furthermore, the relative importance of many of these prognostic factors has been shown to be dependent on the immunophenotype of ALL[3] and the specific therapy given.[27] This ability to predict which children have a high probability of treatment failure, made possible by prognostic factor analysis, has permitted more individualization of therapy.

One of the most powerful predictors of prognosis in most studies is the age of the affected patient. Patients >10 or 11 years of age or <1 to 2 years of age have been noted to fare much worse than children who are between 1½ and 11 years old at the time of diagnosis.[3,28] The reasons for treatment failure in affected patients who are younger or older than average at the time of diagnosis are presently unknown. Some investigators have reported unusually severe drug-associated or radiation-associated toxicity in infants.[29,30] Often, a recommendation for a reduced drug dose is made in these young patients. Nevertheless, it is unknown whether or not such problems contribute to the high relapse rate of affected infants; a recent report suggests that drug dose reduction is not the explanation.[30]

To examine the hypothesis that infants in our studies might have fared worse because of clinical and/or biologic differences in their leukemia, the Pediatric Oncology Group (POG) retrospectively examined their data regarding clinical and biologic features of children (<11 years of age) affected with ALL including: the levels of the WBC and platelet counts, the Hgb level, the presence of massive organomegaly, the incidence of CNS disease at diagnosis, the sex ratio, race, immunophenotype distribution, cytogenetic profiles, French-American-British (FAB) classification, expression of Ia-like antigen and common acute lymphocytic leukemia antigen (CALLA), glucocorticoid receptor levels in blasts, and periodic acid-Schiff (PAS) expression in blasts. We found that infants fared much worse than older children (group 1) with ALL who were given the same therapy and had evidence of more bulk disease, including CNS leukemia at diagnosis. They also often had a biologically different type of acute leukemia (AL) which was usually of L1 morphology and expressed Ia-like antigens, but

was more often PAS$^-$ and CALLA$^-$ than ALL affecting older children.

MATERIALS AND METHODS

After informed consent was obtained, 1,566 newly diagnosed children <11 years of age with esterase-negative and Sudan black B-negative acute leukemia were evaluated between May 1979 and May 1984. The <18-month age cutoff was used to define group 2 because previous POG analyses of its children with ALL revealed a worse prognosis for children who were below this age at the time of diagnosis. Arbitrarily, adolescents (>10 years of age) were excluded from this analysis and will be the subject of a later report. In addition to the routine history, physical examination, laboratory, and radiographic studies which were performed on all patients ($N = 1566$), detailed classification studies were done on lymphoblasts from most children ($n = 936$) at the reference laboratories of the University of Alabama at Birmingham, Duke University Medical Center and John's Hopkins Steroid Receptor Laboratory on leukemia cells obtained at diagnosis from each patient.[31] Only 1,207 (1,117 in group 1 and 90 in group 2) children who were evaluable and who had uniform remission induction therapy with vincristine and prednisone ± L-asparaginase on POG 7623, 7866 or 8036 treatment protocols were used for the analysis of remission induction rates. The subset of 487 affected children (33 infants) with non-B, non-T cell ALL who had been followed for adequate periods of time (see Results section) and were treated on the POG 7623 (ALinC 12) study (see Appendix for details) were used for the analyses of durations of complete remissions.

Immunologic and cytochemical cell markers and glucocorticoid receptors. Wright's–Giemsa–stained leukemic cells were examined morphologically by a panel of five collaborating hematologists and one pathologist and were classified according to FAB criteria.[32] In addition, leukemic cells were examined for Sudan black B,[33] PAS, non-specific esterase, and chloroacetate esterase cytochemical reactivities by standard techniques, for surface immunoglobulin (SIg),[34] and for receptors for sheep erythrocytes (E-R),[35-37] IgG, and for the third component of complement[21,38] by established and quality-controlled techniques at member institutions.[31] At each member institution, cells were stained for SIg, centrifuged onto glass slides, fixed in cold 95% ethanol–5% acetic acid, washed, and mailed submerged in phosphate-buffered saline (PBS) to the University of Alabama at Birmingham's Immunology Reference Laboratory for cytoplasmic immunoglobulin (CIg) testing, as previously described.[39] Heparinized bone marrow samples were placed in tissue culture media and were shipped by express mail to Duke University's Immunology Reference Laboratory to be examined for the expression of Ia-like (HLA-DR) and pan-T (pT) cell markers and CALLA by microcytotoxicity assays using heteroantisera and monoclonal antibodies, as described.[40-42] Glucocorticoid levels in blast cells were also determined.[25]

Definitions. All leukemias were classified into T, B, pre-B or non(T, B, pre-B) cell ALL subgroups according to the following criteria: pre-B cell, if $\geq 10\%$ of marrow lymphoblasts contained CIg; B cell, if $\geq 10\%$ of marrow lymphoblasts had easily detected SIg without cIg (ie, μ heavy chains); T cell, if $\geq 40\%$ of marrow lymphoblasts were lysed by pan-T (pT) heteroantisera (40% above control lysis by cytotoxicity testing). The non(T, B, pre-B) cell group included all patients with ALL not classified by the above criteria, irrespective of the expression of CALLA and Ia-like antigens. However, most of these latter cases expressed Ia-like antigens (97%); overall, most expressed CALLA (90%).

Statistics. Although some inferences are phrased in the text as though one-sided comparisons were made, all significance levels (P-values) reported resulted from two-sided comparisons. The method of Kaplan and Meier was used to construct the life tables and curves.[43] The Mantel-Haenszel statistic was used to compare life tables.[44] If expected cell frequencies permitted, contingency tables were analyzed using the classical chi-square statistic.[45] Otherwise, an exact procedure, based on the chi-square statistic, was used.[46] Distribution of quantitative factors (such as platelet counts and WBC counts at diagnosis) were also analyzed using the Wilcoxon test.[45]

RESULTS

Response to treatment. Forty-seven of 1,117 (4%) children from group 1 and 9 of 90 (10%) infants from group 2 who were evaluable failed to achieve a complete remission in four weeks with vincristine and prednisone (VP) or VP and L-asparaginase therapy ($P = .03$). The duration of continuous complete remission (CCR) for the 454 evaluable children from group 1 and 33 children from group 2 who entered remission and were maintained on POG 7623 (AlinC 12) treatment regimens (described in Appendix) is shown in Fig 1. The median duration of follow-up for those children who remain at risk is three years and 11 months. The duration of CCR for those who were treated according to POG 8036 are not included here since the follow-up time for this study is

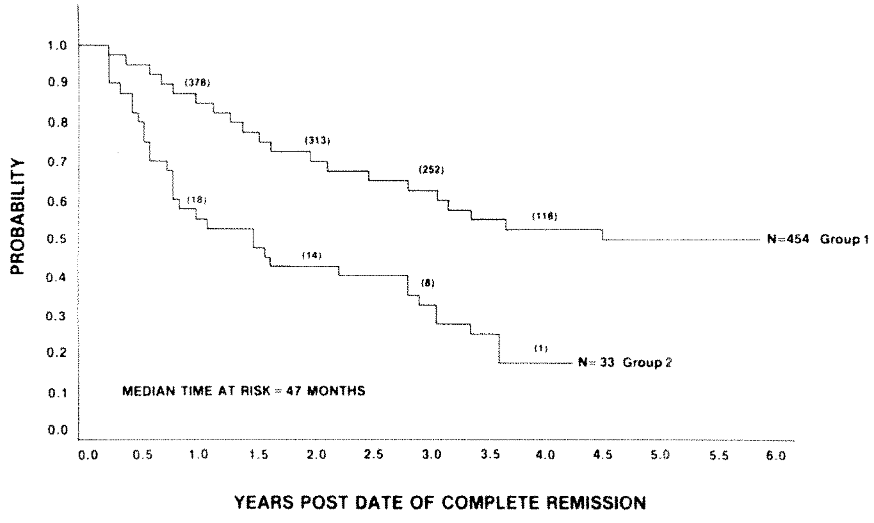

Fig 1. Duration of continuous complete remission (CCR) for patients treated according to POG 7623 with non-T, non-B, acute lymphoid leukemia ($P = .0001$). Failure is defined as relapse at any site or death while in remission. The number of patients who remain at risk at various points in time are noted in parentheses. Group 1, patients >10 years of age; group 2, patients <18 months of age.

short (median = 12 months). It may be seen that infants fare far poorer than do older children $P = .0001$. They also have significantly shorter durations of both bone marrow and CNS remissions ($P < .03$ and $P < .001$, respectively). The three-year CNS remission rate was 66% (SE = .11) for infants and 89% (SE = .02) for children in group 2 and the 3-year bone marrow remission rate for infants was 64% (SE = .11); for children in group 2, it was 74% (SE = .02).

Comparisons of possible clinical prognostic factors between age-defined subgroups of children with ALL. Data in Table 1 illustrate that the infant group is more likely to have a significantly larger proportion of affected individuals who have a high WBC count at diagnosis. Infants also have a higher incidence of massive (respective organ below the umbilicus) hepatomegaly (18% *v* 6%) and splenomegaly (23% *v* 8%) ($P < .001$ and $P < .001$, respectively), lower median platelet counts (36,000/μL *v* 52,000/μL) ($P < .001$) and more CNS disease at diagnosis (11% *v* 4%, $P = .003$). In contrast, there was no significant difference in their sex ratio, racial distribution, incidence of a mediastinal mass, hemoglobin levels at diagnosis, percentage of marrow blasts, or incidence of bone involvement as compared with older children. There was no significant difference in the proportion of infants (29 of 46, 63%) *v* older children (374 of 513, 73%) who were in complete remission at day 14 of induction treatment ($P = .08$) after treatment on POG 8036; however, the number of infants available for analysis was small. Data from patients treated according to POG 8036 were used for this latter analysis, since bone marrow examinations were required on day 14 of treatment on this study only.

Comparisons of laboratory-defined features (group 1 v *group 2).* Data in Table 2 illustrate that infants with non(T, B, pre-B) ALL are more often CALLA$^-$ than older children (group 1), but usually express Ia-like antigens (38 of 39). Furthermore, the data show that most of the children who were CALLA$^-$ (group 2) were in the group who were <1 year of age at diagnosis. In addition, infants (group 2) with pre-B cell ALL had blasts that were CALLA$^-$ significantly more often than those from similar cases of pre-B cell ALL in older children (see Table 2). Table 2 also illustrates that there were no significant differences in distributions within the lineage-specific immunologic groups shown between group 1 and group 2, and between group 1 and group 2 infants <1 year of age. The small group of 12 children with B cell ALL were excluded from this analysis. Table 3 summarizes the limited cytogenetic data available for both groups 1 and 2. No significant difference in ploidy distribution or other cytogenetic features were noted. However, there was a high incidence of unsatisfactory studies and of "normal" results. It is possible that poor-quality banding studies, which were frequently noted, obscured significant differences between the patient groups regarding specific cytogenetic abnormalities such as translocations. No significant differences in the levels of corticosteroid receptors in blast cells or L1 or L2 morphology of the blasts from these patients were observed between patient groups. The blasts from infants, however, were significantly more often PAS– ($P = .02$).

Table 1. White Blood Cell Count Distribution By Age Groups

WBC per μL	Group 1 No of Patients (%)	Group 2 Infants (%)
<10,000	705 (49)	32 (29)
10,000–50,00	482 (33)	27 (24)
50,000–100,000	132 (9)	27 (24)
≥100,000	135 (9)	26 (23)
$P < .0001$		POG 7865 and 8035

DISCUSSION

This study has demonstrated that infants have a much worse prognosis than do children who are older. They enter remission less readily (n = 1,207, $P = .03$) and survive in CCR for shorter periods of time than older children (n = 487, $P = .0001$) (see Fig 1). Infants also have a higher incidence of CNS disease at diagnosis and experience shorter durations of both CNS and bone marrow remissions ($P < .001$ and $P < .03$). Our data also illustrate that infants have more bulk disease (hepatosplenomegaly and higher WBC counts initially) and lower platelet counts than do children from group 1. All of these factors have been associated with a poorer prognosis in other studies.[1,2,4-6,10]

Immunologic marker analysis of the blasts from the infants (group 2) in our study revealed that approximately two-thirds of them have ALL of well-defined cell lineage based upon detection of specific cell markers (CIg$^-$, SIg$^-$, CALLA$^-$, or T cell-specific antigens). The distribution of these well-defined phenotypes of ALL is not significantly different from that seen in older affected children except for the lower incidence of CALLA expression in group 2. However, one third of these infants have AL of FAB L1 morphology, which expresses Ia-like (HLA-DR) antigens but lacks CALLA and CIg expression (see Table 2) and is more often PAS negative. Furthermore, if one considers only infants <1 year of age, more than one-half have CALLA$^-$, CIg$^-$, SIg$^-$, T-antigen$^-$, HLA-DR$^+$ acute leukemia. The lack of CALLA expression by blast cells has been associated with a poor prognosis in some studies.[21,28] No other similarly studied group of affected infants is available for comparison, and only occasional case reports of individual infants who were similarly studied are available.[47] Taken together, these clinical and biologic findings supports the notion that infants often have a biologically different type of acute "undifferentiated" leukemia which appears to be more aggressive than the disease seen in older children and is less responsive to the treatments commonly used for ALL.

Nadler et al[48] have examined B cell-associated and B cell-restricted antigens and, in some cases, the state of the immunoglobulin genes of tumor cells from 138 children and adults with non-T cell ALL. They found that leukemic cells from the patients could be assigned to one of four maturational groups based on sequential patterns of antigen expression: HLA-DR–related Ia-like antigen (Ia) alone (stage I); Ia/B4 (stage II); Ia/B4/CALLA (stage III); and Ia/B4/CALLA/B1 (stage IV). The expression of B cell-restricted antigens (B4 and B1) and rearrangements of Ig heavy chain

Table 2. Incidence of Immune Phenotypes of ALL Within Age Groups of Affected Children

Immunophenotype	Group 1 1.5 to 10 yr No. of Children (%)	Group 2 <1.5 yr No. of Children (%)	Group 2 Patients <1 yr No. of Children (%)

Total	876	60	33

Statistical analysis of data: comparison of immune phenotype distributions (A v B v C) between groups 1 and 2 ($P > .9$) and between group 1 and group 2 patients <1 year of age ($P < .7$]. (B cell patients excluded because of small numbers.) Comparison of distributions of CALLA expression for group 1 v Group 2: $P < .0001$ for children with non(T, B, pre-B) cell ALL; $P = .01$ for children with pre-B cell ALL (see data below).

Ninety-seven percent of patients in group 1 with non(T, B, pre-B) cell ALL expressed Ia-like (HLA-DR) antigens as compared with 97% (38 of 39) of infants (group 2).

*Distribution of CALLA expression by 6-month increments of age in children with non(T, B, pre-B) cell ALL <6 months: 9 CALLA$^-$, 1 CALLA$^+$: 6 to 12 months: 9 CALLA$^-$, 2 CALLA$^+$; 12 to 18 months: 2 CALLA$^-$, 16 CALLA$^+$.

†Ninety-three percent of pre-B cell leukemias expressed CALLA (Group 1, 96%, Group 2, 71%, group 2 infants <1 year of age, 57%).

genes provided strong evidence for the B cell lineage of stages II, III, and IV tumors. They also found normal counterparts for leukemic cells of stages II through IV among fetal and adult bone marrow cells. They concluded that the 4% of their patients who had blasts that expressed only Ia-like antigens (stage I) had leukemias of uncertain lineage, but they speculated that the blasts from this group represented an even earlier stage of pre-B cell differentiation than did those from the IaB4$^+$ subgroup (stage II). No blasts of the stage I patients expressed CIg and results of analyses for immunoglobulin gene rearrangements were not reported for that group. The blasts from 97% of our infants with non(T, B, pre-B) ALL expressed HLA-DR (Ia-like) antigens, but the leukemia cells of 51% of these infants with non(T, B, pre-B) cell ALL did not express CALLA. The blasts from these cases may be analogous to Nadler's stage I, but we cannot say how many are in each stage because testing with the monoclonal antibody B4 was not done. In addition, the blasts of several of our cases were HLA-DR$^+$, CIg$^+$, and CALLA$^-$. This phenotype does not follow the maturational sequence proposed by Nadler, since the expression of CIg would be expected to occur concomitant with or after the expression of CALLA. This may represent an aberrant phenotype. Further studies are needed to define more clearly the cell lineage and maturational stage of the leukemic cells of this group of patients with AL. Blasts from one of the affected infants with AL included in this study have been examined to determine the state of the Ig genes and expression of terminal deoxynucleotidyl transferase (TdT), the blasts were also examined by electron microscopy (EM). The Ig heavy chain genes were rearranged, TdT was expressed, and EM findings compatible with common or pre-B cell ALL were observed, suggesting that this case was of early B cell lineage.[49] Similar studies of the blasts from more of these infants would be of interest.

Table 3. Results of Cytogenetic Studies Within Age Groups of Children With ALL

Ploidy	Group 1 1.5-10 yr (%)	Group 2 <1.5 yr (%)
Normal	316 (63)	24 (59)
Hyperdiploid	107 (21)	11 (27)
Hypodiploid	25 (5)	1 (2)
Pseudodiploid	40 (8)	5 (12)
Constitutional abnormality*	14* (3)	0

Distribution overall: P = NS; pseudodiploidy, group 1 v group 2: $P = .37$.

*The 14 constitutional abnormalities were: 11 Downs' syndrome, 1 Klinefelter's syndrome, 2 others.

Reaman et al[30] have presented data regarding certain clinical features and the outcome of 115 infants (<1 year of age) treated on Children Cancer Study Group (CCSG) protocols. These infants had higher WBC counts and more CNS disease at diagnosis than did the older children in their studies. The infants with CNS disease fared poorly: 82% subsequently experienced a bone marrow relapse. Furthermore, although 96.5% of these infants achieved complete remission, only 30 of them did so by day 14 of induction, and the induction death rate was 4%. Drug dosage modification occurred in only 9% of these infants. The median duration of remission was 8.5 months. In addition, there was a similarly high CNS relapse rate in infants who received cranial irradiation (22%) or only intrathecal chemotherapy (23%) as a part of their CNS prophylaxis. The testicular relapse rate was 6%. Relapse-free survival at three years from diagnosis was only 12.5%, with only eight infants continuing in CCR >1 year following cessation of therapy. Severe neuropsychologic side effects were noted in at least 50% of these infants.

The findings in our population of infants with ALL are similar to those of Reaman et al in that the WBC counts of the patients (see Table 2) were higher, as was their incidence of CNS disease (11%) and CNS relapse rate (24%). The 8.5-month median duration of remission noted in the infants reported by Reaman et al is similar to the 10-month median duration of remission noted in our infants who are <1 year of age. The CCR rate at 3 years of the infants in the CCSG study was 12.5%, which may be compared to a CCR rate of 25% at 3 years and 8% at 4 years in our infants who were <1 year of age. We do not have specific data regarding neuropsychologic side effects and drug dosage received in our patients. The clinical findings of the infants in our study extend those reported by Reaman et al in that we noted a significantly higher incidence of massive hepatosplenomegaly and lower platelet counts.

It is clear from our studies that infants with morphological criteria, with or without immunologic criteria for the diagnosis of ALL, have a very poor prognosis when treated with chemotherapy designed for children with ALL (Fig 1). Our infant population entered remission less well and experienced more CNS and bone marrow relapses than did older children. The immunologic marker data revealed that approximately two thirds of these infants have AL of well-defined lymphoid lineage, whereas one third of them have an AL of uncertain lineage. The latter expresses Ia-like antigens without CALLA or CIg and is more often PAS$^-$ than is the ALL seen in older children. These infants appear to have a biologically different form of AL, the lineage of which remains uncertain at present. We believe that the biologic and clinical differences noted in these infants with ALL predict and explain in part their poor prognosis. Clearly, better therapy is needed for these infants since currently most succumb to their disease very quickly despite aggressive chemotherapy.

APPENDIX

Dosage and Therapy Schedule for ALinC 12 (POG 7623)

	Regimens 1 and 2*	Regimen 3
Number of group 1 (group 2) patients treated†	294 (34)	172 (51)
Phase of treatment		
Induction	V, 2mg/M^2/IV/ wk × 4, P, 60mg/ M^2/day p.o. × 28 and L-asp, 10,000 U/kL/ wk × 2	VP
Consolidation	6MP, 50mg/M^2/day p.o. until CNS therapy complete	L-asp, 6,000 U/M^2/ d × 14 CTX, 1g/ M^2/IV on days 1 and 14, followed by IV MTX, 15mg/M^2/day × 4 q 2 wk × 6
Treatment of CNS subclinical	IT MTX, 12mg/ M^2 28/wk × 5 Cranial RT†	§Triple IT medicine q 2 wk × 6
Continuation treatment (3 yr)	6MP, 50mg/M^2/day p.o. MTX, 20mg/ kL/week p.o.	Same as in Regimen 1
Systemic reinforcement	V, 2mg/M^2/IV/wk × 3 P, 40mg/M^2/ day p.o. × 21	Same
CNS reinforcement	None	§Triple IT, q 8 wk × 3 yr

Ara-C, arabinosyl cytosine; 6TG, 6 thioguanine; CTX, cyclophosphamide; P, prednisone, V, vincristine; L-asp, L-asparaginase; 6MP, 6 mercaptopurine; MTX, methotrexate; IT, intrathecal, q, every; CNS, central nervous system; RT, radiation therapy.

*Regimen 2 was identical to regimen 1 except that the WBC count was kept between 3,000 and 4,500/μL in regimen 1 and between 1,500–3,000/μL in regimen 2. (No difference in relapse incidence has been noted between these patient groups.)

†Only patients receiving all phases of therapy are shown here and in Fig 1.

‡Cranial RT: children >2 years, 2,800 rad; children 1 to 2 years, 2,000 rad; and children <1 year, 1,500 rad.

§Triple intrathecal (IT) MTX 15mg/kL, Ara-C 30mg/kL, hydrocortisone 15mg/kL.

Abnormal Spectrin in Hereditary Elliptocytosis

By Sally L. Marchesi, William J. Knowles, Jon S. Morrow, Marcia Bologna, and Vincent T. Marchesi

An abnormal α subunit of erythrocyte spectrin has been described in hereditary pyropoikilocytosis (HPP), a rare hemolytic anemia characterized by erythrocyte budding and fragmentation. In HPP spectrin, the N terminal domain of the α subunit (α I T80) shows increased susceptibility to tryptic digestion, resulting in cleavage to a 50,000-d peptide, presumably due to a change in primary structure of the α I domain which alters conformation and generates the new cleavage site. The functional result of this conformational alteration is marked impairment of spectrin oligomer formation in vitro, consistent with the established role of α I T80 in spectrin self-association. In the present study, we demonstrate an abnormal spectrin α subunit in two kindreds with hereditary elliptocytosis (HE) that is qualitatively identical to HPP spectrin. Clinical expression of HE in these families ranges from mild elliptocytosis without hemolysis to severe poikilocytic hemolytic anemia clinically resembling HPP. In all affected individuals, a fraction of α I T80 is abnormal, as shown by its cleavage during mild tryptic digestion to the 50 kd peptide described in HPP; the fraction of α I T80 affected is directly proportional to the severity of clinical expression of HE. Spectrin oligomer formation is likewise impaired to a degree which correlates with hematologic disease. One of the HE kindreds studied demonstrated polymorphism in the spectrin α II domain, previously described as a frequent occurrence in blacks. This family also demonstrates a variant α III domain in spectrin that has not previously been described. We conclude that the abnormality in the α I domain originally described in HPP spectrin is shared by a subset of patients with HE; the severity of clinical expression, ranging from mild nonhemolytic HE to poikilocytic hemolytic anemia, is related to the fractional quantity of the α subunit that is affected.

© 1986 by Grune & Stratton, Inc.

HEREDITARY elliptocytosis (HE) has long been thought to be a genetically determined disorder of the red cell membrane; however, until recently, there has been no direct evidence to support this hypothesis. Although inheritance of HE occurs in an autosomal-dominant fashion, its expression is extremely variable, the number of elliptocytes in the peripheral smear ranging from <10% to 100%. Compensated hemolysis is common, but significant anemia occurs in only a small number of patients. Poikilocytic variants of HE with severe hemolysis may occur in early childhood in kindreds with elliptocytosis; the peripheral smears of these children show marked microcytosis, pyknocytosis, and fragmentation of erythrocytes.[1-6] In some of these cases, both parents have HE, are consanguineous, or both, whereas in others only one parent has HE or both parents are normal hematologically. Frequently, the severity of the hemolysis ameliorates with age, and the patient develops more typical elliptocytosis with mild to moderate hemolysis.

In 1975, Zarkowsky et al[7] described three children from two kindreds with severe hemolytic anemia characterized by striking poikilocytosis, pyknocytosis, microspherocytes and budding forms. One parent had mild elliptocytosis, whereas the other three parents were normal. Because the morphologic changes in the peripheral blood of the patients resembled that seen in heat injury, heat-induced fragmentation of the patients' cell was studied; it was found that the patients' cells fragmented at 45 °C in contrast to 49 °C for normal cells, and the syndrome was thus termed hereditary pyropoikilocytosis (HPP). Calorimetric studies show a major structural transition in HPP ghosts and spectrin at 45 °C compared with the normal transition at 49 °C.[9] These studies strongly suggested that spectrin was abnormal in HPP.

We and others[10-13] have reported the analysis of erythrocyte spectrins from HPP patients and their relatives, some whom have HE, by two-dimensional isoelectric focussing (IEF) sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) of intermediate-sized tryptic peptides. These studies have demonstrated an alteration in affected subjects of the *N*-terminal 80,000-dalton domain of the spectrin α subunit (α I T80), which has been shown to bind to dimeric spectrin to promote formation of spectrin oligomers.[14] In a previous study from our laboratory,[10] spectrin from HPP patients and from one sibling with HE showed increased susceptibility of α I T80 to mild tryptic digestion, with production of 50 kd and 21 kd peptides which are not generated in significant amounts from normal spectrin under the conditions used. Similar observations have been made in HE and HPP spectrin by Lawler et al.[12,13] Spectrin from these individuals demonstrates decreased ability to self-associate to form tetramer and higher oligomers, as shown either by an increased content of dimer relative to higher forms in fresh extracts at 4 °C[5,11-13,15] or by impaired concentration-dependent oligomer formation under isotonic conditions at 30 °C.[10] These studies have been interpreted to mean that a molecular alteration (amino acid substitution, deletion) in α I T80, as evidenced by the abnormal susceptibility to tryptic digestion, is responsible for decreasing oligomer stability and consequently decreased stability of the membrane skeleton, resulting in red cell shape change, fragmentation, and hemolytic anemia.

A relationship between HPP and HE is suggested by: (1) the clinical resemblance of HPP to poikilocytic infantile variants of HE, some of which have been thought to represent homozygous HE[1,2,4]; (2) the occurrence of HE in parents or other family members of some patients with HPP[7,10,13,15]

and (3) a mildly decreased thermal stability of red cells from some kindreds with HE, in which fragmentation occurs at 47 °C to 48 °C.[8,16]

In a strict sense, the term HPP should not be applied to patients with poikilocytic variants of HE unless heat stability studies have been performed; however, these varients of HE (which may be called poikilocytic hemolytic elliptocytosis (PHE)) should probably be grouped with HPP until the specific molecular pathologies producing this clinical picture are better defined.

We report here studies of spectrin from two kindreds with hereditary elliptocytosis; one family of five (a mother and four children) which includes two individuals with compensated hemolysis, and a second family (grandmother, mother, child) with elliptocytosis that is expressed in the child as a severe poikilocytic hemolytic anemia. The spectrin of all affected family members shows an alteration in the N-terminal 80-kd domain of the α subunit (α I T80), which is identical qualitatively to that previously reported for hereditary pyropoikilocytosis, but which involves a smaller fraction of the total α subunit.

MATERIALS AND METHODS

Blood collection, preparation of red cell ghosts and extraction of spectrin. Blood was collected by venipuncture into ACD anticoagulant; informed consent was obtained from all donors and the quantity of blood drawn was appropriate to the estimated blood volume and hematocrit of the subject. Red cell ghosts were prepared by lysis of washed red cells for 30 minutes at 0 °C in 10 to 15 vol of 5 mmol/L of sodium phosphate, 1 mmol/L of EDTA pH 8.0 containing 130 μmol/L of phenylmethylsulfonyl fluoride (PMSF) and 0.1 mmol/L of diisopropyl fluorophosphate (DFP), followed by three washes with the same buffer. Spectrin was extracted by 48-hour dialysis of ghosts at 4 °C into 0.1 mmol/L of EDTA, pH 9.4, containing 130 μmol/L of PMSF and 0.1 mmol/L of DFP. The vesiculated ghosts were removed from the spectrin extract by 2× centrifugation at 48,000 g for 60 minutes at 4 °C. The spectrin extract was then dialyzed into buffer containing 10 mmol/L of Tris, 20 mmol/L of NaCl, 130 mmol/L of KCl, 1 mmol/L of EDTA, 1 mmol/L of β-mercaptoethanol, 30 μmol/L of PMSF, and 0.2 mmol/L of DFP at pH 7.4, and stored on ice.

Tryptic digestion of spectrin. Aliquots (200 μg) of spectrin extract were dialyzed against 20 mmol/L of Tris-HCl pH 8.0, and 1 mmol/L of 2-mercaptoethanol for 20 hours at 4 °C. Trypsin (TPCK-treated, 206 units/mg; Worthington) was added at an enzyme-substrate ratio of 1:20 wt/wt. The reaction was carried out for 90 minutes at 4 °C and was terminated by adding DFP to a concentration of 1 mmol/L and cooling to −80 °C. The digests were lyophilized and stored at −20 °C prior to electrophoresis.

PAGE. Lyophilized spectrin tryptic digest (200 μg) was solubilized in 75 μL of a solution containing 9 mol/L of urea, 2% Triton, 5% β-mercaptoethanol and 2.4% ampholines (LKB Instruments, Inc, Rockville, Md) and focused on 3 × 20 mm polyacrylamide gels according to O'Farrell[17] for 5,700 volt hours. The pH gradient extended from 7.2 to 4.5 and was formed as previously described.[10] After electrophoresis, the gels were equilibrated for ten minutes in 10% glycerol, 3% SDS, 1 mmol/L of EDTA and 2% β-mercaptoethanol before electrophoresis in the second dimension on 10% to 15% acrylamide gradients, using Laemmli buffers.[18]

Analysis of spectrin oligomers. Formation of spectrin oligomers was studied by electrophoresis of extracted spectrin on 2% to 4% gradient nondenaturing polyacrylamide slab gels at 4 °C. The gels were electrophoresed at 50 V for 48 hours in buffer containing 40 mmol/L of Tris, 20 mmol/L of Na acetate, and 2 mmol/L of EDTA pH 7.4.[19] Spectrin extracts prepared at 4 °C as described above were concentrated to 12 to 14 mg/mL by vacuum dialysis against 10 mmol/L of Tris, 20 mmol/L of NaCl, 130 mmol/L of KCl, 1 mmol/L EDTA, 0.5 mmol/L of NaN_3, pH 7.4. Serial dilutions of spectrin in the same buffer were incubated for three hours at 30 °C prior to electrophoresis. In some cases, nondenaturing gels were run in the second dimension on 7% to 12% acrylamide gradients in SDS according to Laemmli.[18]

Quantitation of spectrin oligomers and peptides from Coomassie blue-stained acrylamide gels was performed by elution of excised gel slices with 1.0 mL of 25% pyridine for three to four days until the gel slice was colorless. Optical density at 700 nm of the eluates was measured in a Varian DMS 90 spectrophotometer.

I^{125} peptide maps. Two-dimensional maps of I^{125}-labeled limit chymotryptic peptides were prepared from intermediate-sized tryptic peptides cut from two-dimensional polyacrylamide gels. Na ^{125}I (carrier free, 350 to 600 mCi/mL) was obtained from Amersham (Arlington Heights, Ill). Labeling of excised gel bands was performed by the method of Elder[20] with modifications.[21] Digestion with chymotrypsin and two-dimensional cellulose peptide maps were formed as previously described.[21]

NTCB cleavage. Spectrin was solubilized in 7 mol/L of guanidine, 200 mmol/L of Tris HCl, and 1 mmol/L of EDTA at pH 8.0, and was cleaved at cysteine residues by 2-nitro-5-thiocyanobenzoic acid (NTCB) at a concentration 10 times the cysteine content. After one-hour incubation at RT, the pH was raised to 9.0, and the solution was incubated at 37 °C overnight. The reaction was terminated by addition of 50 mmol/L of β-mercaptoethanol. The spectrin fragments produced were analyzed by two-dimensional IEF/SDS-PAGE and the peptide mapping procedure described above.

Photomicrographs. Wright's-Giemsa stained blood smears were photographed at 200 × magnification on a Olympus BH-2 photomicroscope.

RESULTS

Erythrocyte spectrin obtained from 22 members of seven kindreds with hereditary elliptocytosis has been analyzed by mild tryptic digestion at 0 °C followed by two-dimensional (IEF/SDS) PAGE of the intermediate-sized tryptic peptides produced. When applied to normal spectrin, this technique generates a map of >50 well-resolved peptides with mol wts ranging from 80 kd to 12 kd.[21] Limit chymotryptic mapping of these peptides combined with generation of overlap peptides obtained by enzymatic and chemical cleavage has led to construction of a model of the spectrin heterodimer that includes five major trypsin-resistant domains within the α subunit and four major domains within the β subunit. These are identified in Fig 1. The α I domain is an 80 kd peptide which is relatively resistant to further proteolysis under the mild conditions used (see Fig 1). There is, however, some cleavage of α I T80 to produce a 74 kd peptide just below and at the same IEP as α I T80. The derivation of the 74 kd peptide from α I T80 has been shown by limit peptide mapping and by monoclonal antibody blot.[22] α I T74 is frequently seen in digests of normal spectrin, but is variable in quantity.

Two-dimensional peptide maps of spectrin obtained from three of seven HE kindreds studied were normal except for polymorphism in the α II 46 kd domain (α II T46) previously described in blacks.[23] Spectrin from affected members of two

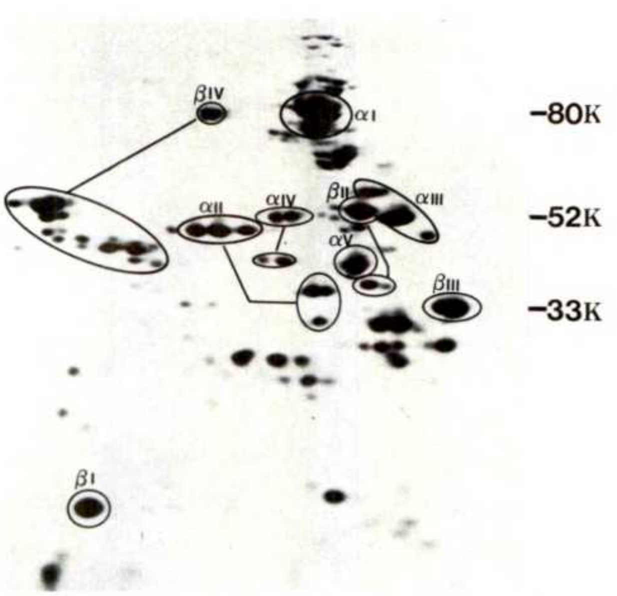

Fig 1. Two-dimensional IEF/SDS polyacrylamide gel electrophoresis of intermediate sized tryptic peptides of spectrin extracted from normal red cells. The major domains of α and β subunits, as defined by mild tryptic digestion, are shown; in some cases, peptides derived from further tryptic cleavage of a parent domain are also shown.

other kindreds with HE showed variably decreased quantities of the 80 kd domain of the α subunit (α I T80) and appearance of a new 50 kd peptide at approximately the same isoelectric point which was previously shown by limit peptide mapping to be derived from the α I 80 kd domain.[10] Concentrated spectrin of affected family members also showed a reduction in oligomer formation of varying degrees when analyzed over a concentration range of ~ 1 mg/mL to 14 mg/mL. These changes are qualitatively similar to those previously reported for patients with hereditary pyropoikilocytosis (HPP), although in no case was all of the α subunit affected as has been seen in HPP.[10] These families are reported in detail below. The remaining two families with HE showed a different structural alteration in the α I domain, which will be reported separately.

Family R. Family R (Fig 2A) is Puerto Rican and consists of a mother and her four children. M.R. Sr is a 46-year-old woman with hematocrits of 36% to 40%, reticulocyte count of 1.3% to 2.1% and peripheral smears showing slight anisocytosis and polychromasia but no elliptocytes. A.R., her 19-year-old son, had hyperbilirubinemia at birth; when he was 6 months of age, his hemoglobin was 9 g/dL, and the smear showed marked elliptocytosis and poikilocytosis. Between the ages of 5 and 17, his hematocrit rose to normal (>40%), and the smears now show typical elliptocytosis. His bilirubin is normal, but haptoglobin is 0 to 10 mg/dL (normal 20 to 200 mg/dL). W.R., 16 years old, has a hematocrit of 42%, reticulocyte count of <1%, some ovalocytic erythrocytes, and a haptoglobin of 31 mg/dL. M.R. Jr, 14 years old, has hematocrits ranging from 33% to 39%, with reticulocyte count of 1.5% to 3%, haptoglobin of 0 and 6 mg/dL, and smears showing marked elliptocytosis. A fourth child, S.R., 12, has a hematocrit of 39%, a reticulocyte count of 0.2%, and a normal smear. The father was not available for study. Peripheral smears from this family are shown in Fig 3A through C.

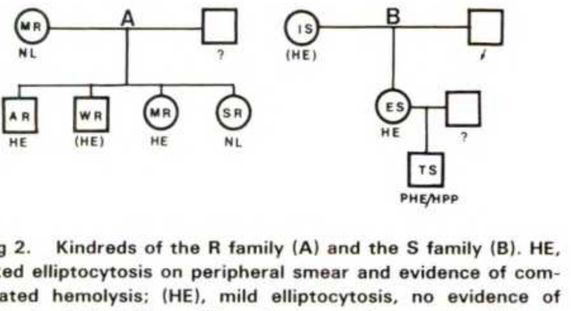

Fig 2. Kindreds of the R family (A) and the S family (B). HE, marked elliptocytosis on peripheral smear and evidence of compensated hemolysis; (HE), mild elliptocytosis, no evidence of hemolysis; PHE/HPP, poikilocytic hemolytic anemia clinically resembling HPP.

Family S. Family S (Fig 2B) is black and consists of a child, his mother, and maternal grandmother. I.S. is a 57-year-old woman with ovalocytes and occasional fragments on smear (Fig 3D). Her hematocrits range from 35% to 40% with reticulocyte count of 1.5%, and a haptoglobin of 77 mg/dL. Her daughter, E.S., 30 years old, had a hematocrit of 24% at one year of age with a reticulocyte count of 5%; the smear showed marked elliptocytosis, anisocytosis, and poikilocytosis. Her hematocrit gradually rose; at 28 years of age, she had a hematocrit of 34% with a reticulocyte count of 2.4% and a haptoglobin of 0. The smear continues to show marked elliptocytosis (Fig 3E) but without the poikilocytosis seen earlier. T.S., the 12-year-old son of E.S., developed hyperbilirubinemia at birth requiring exchange transfusion. His peripheral smears showed marked poikilocytosis, microcytosis, and fragmentation. At 2 weeks of age, his hematocrit was 22% and his reticulocyte count was 6%. Hemoglobin was AA, G6PD was normal, and Coombs test was negative. At 4 months of age, he developed hepatosplenomegaly. He required five transfusions during the first 6 months of life for hematocrits of 15%; at 2½ years of age, he was transfused for a hematocrit of 12% during a viral infection. Between the ages of 4 and 9 years, his hematocrits were stable at 27% with a reticulocyte count of 14% to 19%. He underwent splenectomy at age 10. Since then, his hematocrits have been 33% to 40% with reticulocyte counts of 1% to 3%. $HgbA_2$ is normal but hgbF is 23% and Heinz body prep is negative. The smear continues to show marked elliptocytosis, poikilocytosis, and pyknocytes (Fig 3F), reflected in an MCV of 54 fL. Although the clinical history of T.S. resembles HPP, tests of thermal stability of his red cells were not performed. The father of T.S. was not available for study, and the maternal grandfather is deceased.

Tryptic digests of HE spectrin. Two-dimensional IEF/SDS-PAGE of intermediate tryptic peptides of family R spectrin is shown in Fig 4. The spectrin of M.R. Sr (Fig 4A) is normal, showing a full complement of the α I 80 kd peptide. The spectrins of A.R. and M.R., Jr (Fig 4B and D), the two children with compensated hemolytic HE, show a moderate decrease in quantity of the α I T80 peptide and a marked increase of a 50 kd peptide with several isoelectric points, present in trace quantities in control spectrin (Fig 1)

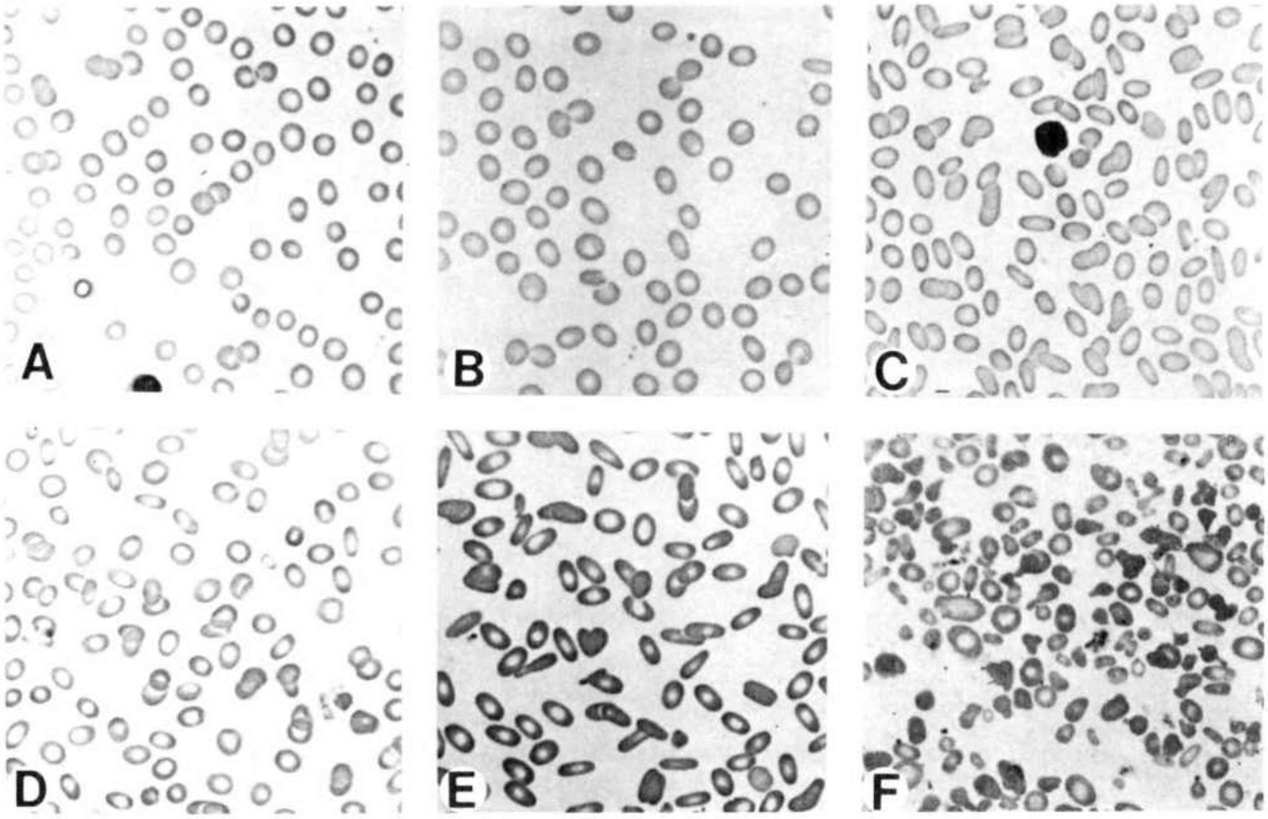

Fig 3. Peripheral blood smears stained with Wright's-Giemsa. R family (A through C): (A) S.R., normal; (B) W.R., mild HE; (C) A.R., hemolytic HE. S family (D through F): (D) I.S., mild HE; (E) E.S., hemolytic HE, (F) T.S., poikilocytic HE (HPP).

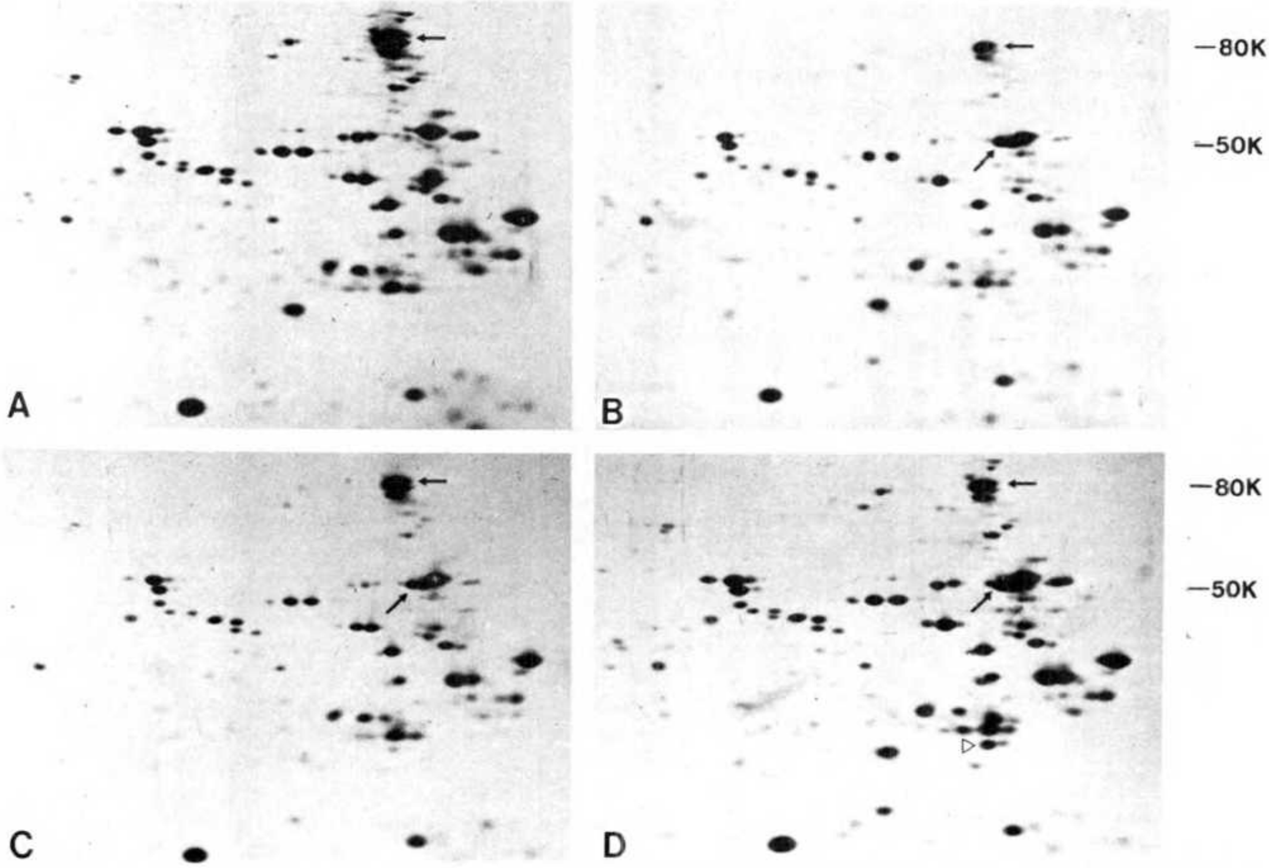

Fig 4. Tryptic peptides of spectrin from members of family R electrophoresed in two dimensions IEF/SDS polyacryamide gel electrophoresis: (A) M.R., Sr, normal; (B) A.R., and (D) M.R., Jr, with marked elliptocytosis and compensated hemolysis; (C) W.R., with ovalocytosis, no hemolysis. Arrows indicate the α I T80 and 50 kd peptides (multiple isoelectric forms). α I T21 (▷) is shown in Fig 4D.

and in the unaffected mother (Fig 4A). W.R., with mildly elliptocytic cells and no evidence of hemolysis, also shows the abnormal α I 50 kd peptide (Fig 4C). Anti-α I T80 monoclonal antibody (23) binds both α I T80 and α I T50 on Western blot of a tryptic digest of AR spectrin (data not shown) consistent with the limit peptide mapping results of Knowles et al,[10] establishing α I T50 as a degradation product of α I T80.

Figure 5 shows the intermediate tryptic peptides of spectrin from family S. I.S. spectrin (Fig 5B) shows a moderate reduction in α I T80, whereas E.S. and T.S. spectrin (Fig 5C and D) show distinct reductions in the quantity of α I T80: in Fig 5D, α I T74 is relatively increased. All three family members show the prominent α I 50 kd peptide observed in affected members of family R.

A second (21 kd) cleavage product of α I T80, identified in limited tryptic digests of spectrin from patients with HPP reported earlier,[10] has been identified by peptide mapping from spectrin digests of members of the R and S families and is demonstrated in Fig 4D and 5B; it can be identified in variable amounts in digests of all affected family members.

The increased susceptibility of the α I 80 kd domain to proteolytic cleavage and the production of the 50 kd and 21 kd peptides observed in these families closely resembles our earlier findings[10] and those of others[11-13] for HPP spectrin, but appears to involve variable percentages of the α subunit. In at least three of the HPP patients reported,[10,12] intermediate tryptic digests showed no residual α I T80, whereas in the R and S families, and in some other patients with HPP,[10,12,13] residual α I T80 is seen in varying degrees. Spectrin peptides α I T80, α I T74, and α I T50 were cut from two-dimensional gels of tryptic digests from the R and S families, and the protein content was quantified by measuring pyridine-eluted Coomassie blue stain (see Methods section). The results are shown in Fig 6, in which α I T50 and α I T74 are expressed as a mole fraction of the total α I

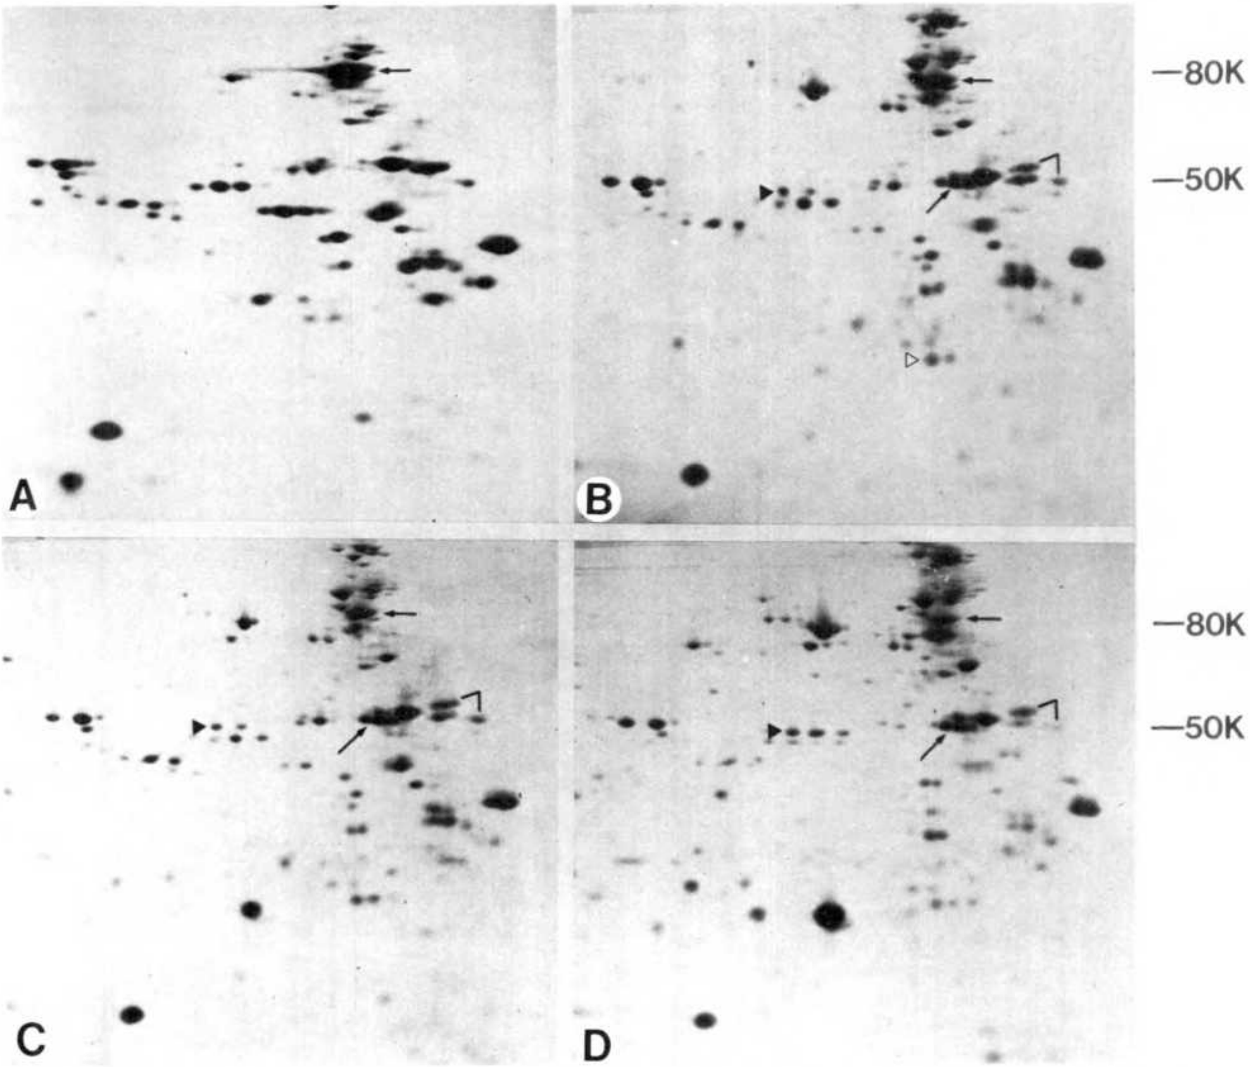

Fig 5. Spectrin tryptic peptides from members of family S electrophoresed in two dimensions IEF sodium dodecyl sulfate polyacrylamide gel electrophoresis: (A) normal spectrin; (B) I.S. with mild elliptocytosis, no hemolysis; (C) E.S. with marked elliptocytosis and compensated hemolysis; (D) T.S. with marked poikilocytosis and hemolytic anemia. Arrows indicate α I T80 and 50 kd peptides in B, C, and D. αIT21 (▷) is shown in Fig 5B. Fig 6. Quantitation by pyridine elution of Coomassie Blue dye of the 50 kd and 74 kd peptides in tryptic digests of spectrin from S and R families, expressed as mole fraction of the total α I T80 domain represented on the gel. Data on T.S. and A.R. are taken from three and two digests, respectively; others are derived from a single digest. Initials of family members are placed in order of decreasing severity of clinical expression of HE for each family.

domain represented on the gel. The initials of the subjects are arranged in order of decreasing severity of hematologic disease within each of the two families. The data shown are taken from one to three two-dimensional gels of spectrin tryptic peptides from each family member and controls. Subsequent quantitation of α I peptides of multiple (three to seven) tryptic digests of spectrin from T.S., E.S., A.R., and controls gave similar results.

It is evident that the mole fraction of α I T50 is highest in the patients from each family with the most severe expression of HE (T.S., E.S., A.R., M.R.) and decreases with decreasing severity of hematologic abnormality. Although α I T74 is increased in some of the tryptic digests of members of these families (as illustrated in 5D [T.S.]), the cleavage of α I T80 to α I T74 is variable in degree in our experience both in normal and HE families. This is shown in Fig 6 (bottom), which expresses the mole ratio of α I T74 to total α I domain peptides from tryptic digests of the S and R families.

Additional α spectrin variants in S family. In addition to the α I T80 abnormality described above, the S family also shows polymorphism in the α II T46 domain of the type previously reported to be common in blacks.[23] In Fig 5A, the α II domain type I migrates as 46 kd peptides at several isoelectric points with cleavage products of 35 kd and 30 kd, and is the type seen in spectrin of all (>100) white subjects studied to date (see also Fig 1). Spectrin of E.S. and I.S. (Figs 5 B and C) shows double heterozygosity for α II T46 types 1 and 2; in type 2, the α II domain migrates as 50 kd, 39 kd, and 35 kd peptides with isoelectric points more basic than α II T46, 35 and 30 (type 1). T.S. spectrin (Fig 5D) is heterozygous for α II T46 types 2 and 3; in the latter, apparent mol wt of α II increases without a change in isoelectric point.

All of the members of the S kindred also show variant α III domain peptides not previously described. A new peptide is seen above and at the same isoelectric point as the normal α III T52 as well as a new α III cleavage product (Fig 5 B through D; see Fig 1). I^{125}-labeled limit chymotryptic maps of the larger peptide (α III T56) are identical to normal α III T52 shown in Fig 7. This α III variant has been seen to date in four other individuals (three kindreds) all of whom are black. Three of these subjects have HE or poikilocytic hemolytic anemia consistent with HPP, and their spectrin shows the α I T80—α T50 cleavage described above, as well as variant α II domains. One of these patients, K.B., was previously reported.[10] Thus, the spectrin of these individuals has alterations in the three of the five domains of the spectrin α subunit.

A number of other differences are apparent on two-dimensional gels of spectrin tryptic digests from normal individuals. These include variability in degree of digestion of the α IV domain and variable intensity of many of the peptides of <30 kd. These differences, which occur randomly, in part reflect differences in protein load, as well as other variables inherent in the experimental technique.

Localization of α I T50 within the α I domain. Cleavage of spectrin at cysteine residues with NTCB followed by two-dimensional IEF/SDS-PAGE yields a complex map of peptides with mol wts between 90 kd and 6 kd. Peptide mapping of some of the NTCB peptides has been performed to identify their location within the domain structure of the spectrin molecule.[21] A 67 kd NTCB peptide has been found by peptide mapping of I^{125}-labeled limit chymotryptic peptides to contain most of the iodinated spots from the α II domain as well as some of the map of α I T50 from HPP spectrin, suggesting that α I T50 is located adjacent to the α II domain. Peptide maps of NTCB 67, α II T46, and α I T50 are shown in Fig 8. The peptide map tracing shows those peptides from α I T50 and α II T46 which are also found in

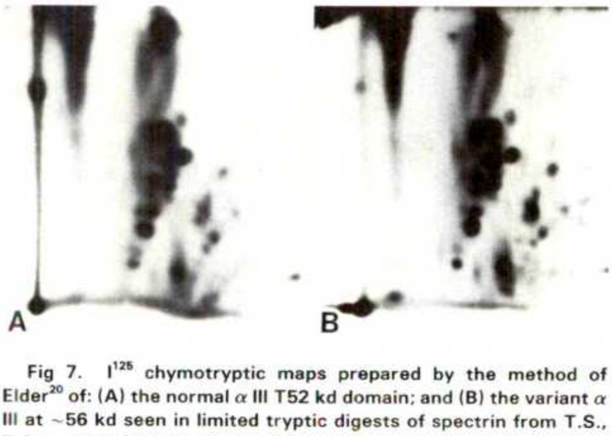

Fig 7. I^{125} chymotryptic maps prepared by the method of Elder[20] of: (A) the normal α III T52 kd domain; and (B) the variant α III at ~56 kd seen in limited tryptic digests of spectrin from T.S., E.S., and I.S. (Fig. 5B through D).

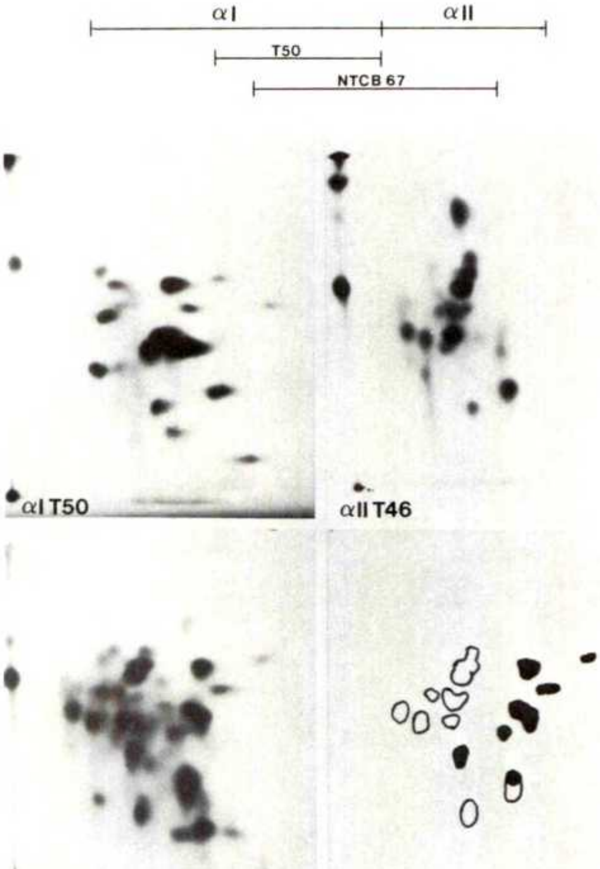

Fig 8. Peptide maps of I^{125}-labeled limit chymotryptic peptides derived from α I T50, α II T46, and NTCB 67 kd peptides. Horizontal axis, electrophoresis; vertical axis, chromatography. The map tracing is a composite of the α I T50 limit peptides (●) and α II T46 limit peptides (○) which appear in NTCB 67. Line drawing at top illustrates the relative locations of the α I and α II domains, α I T50, and the NTCB 67 peptide.

NTCB 67K. These results establish the proximity of α I T50 to the α II domain, as shown in the molecular model at the top of Fig 8. Placement of α I T50 from HPP spectrin in the C terminal half of the α I domain agrees with sequencing data performed on α I T50 derived from normal spectrin (discussed later).

Oligomer formation from HE spectrin. The ability of spectrin heterodimers from family R and family S to form higher oligomers was analyzed by incubation of spectrin at concentrations between 0.8 and 14 mg/mL in isotonic buffer at pH 7.4 for three hours at 30 °C prior to nondenaturing gel electrophoresis. Results are seen in Figs 9 through 11.

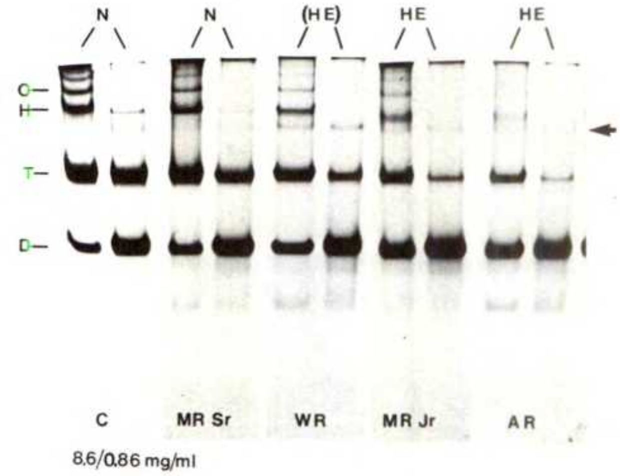

Fig 9. Self-association of spectrin from members of family R. Crude spectrin extracts from family members designated by initials and from a normal unrelated control donor were concentrated and incubated at 30 °C for three hours at 8.6 mg/mL (left lanes) and 0.86 mg/mL (right lanes); 75 μg of each sample was loaded on 2% to 4% acrylamide gels and was run for 48 hours in Na acetate buffer pH 7.4. D, dimer; T, tetramer; H, hexamer; O, octamer. Arrow (right) indicates nonspectrin protein which migrates near hexamer in this gel system. Other nonspectrin proteins are seen migrating ahead of spectrin dimer.

Figure 9 shows oligomer formation by spectrin from the R family at concentrations of 0.86 and 8.6 mg/mL. It can be seen that spectrin from a normal individual (C) and from the unaffected mother, M.R. Sr, when incubated at the 8.6 mg/mL (left lanes) forms higher oligomers, whereas the predominant forms of spectrin at 0.86 mg/mL (right lanes) are dimer and tetramer. Spectrin from A.R. and M.R., Jr, who have compensated hemolytic HE, forms less tetramers than normal at low concentrations and forms less oligomers at high concentration. Spectrin of W.R. (mild nonhemolytic HE) forms oligomers normally at the higher concentration; however, at low concentration, it has a moderately increased dimer-tetramer ratio.

Figures 10 and 11 show oligomer formation by spectrin from the S family. Both T.S. and his mother, E.S., have markedly impaired oligomer formation in vitro over a wide

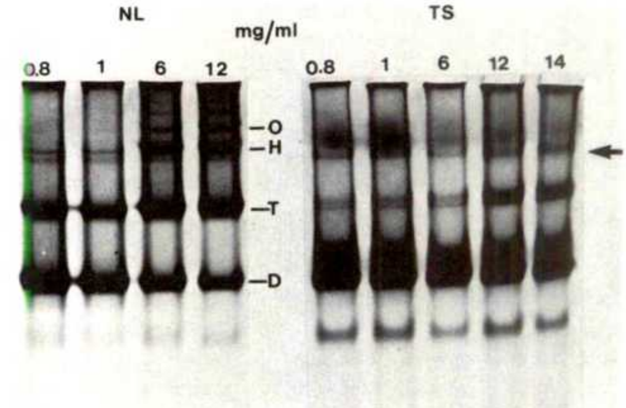

Fig 10. Self-association of normal spectrin and spectrin from T.S. with poikilocytic HE and hemolytic anemia. Crude spectrin extracts were incubated at concentrations from 0.8 to 14 mg/mL at 30 °C for three hours and were then electrophoresed on 2% to 4% nondenaturing acrylamide gels. D, dimer; T, tetramer; H, hexamer. Arrow indicates nonspectrin protein migrating just behind hexamer. Other nonspectrin proteins are seen migrating ahead of spectrin dimer; globin migrates as a diffuse band at the top of the gel.

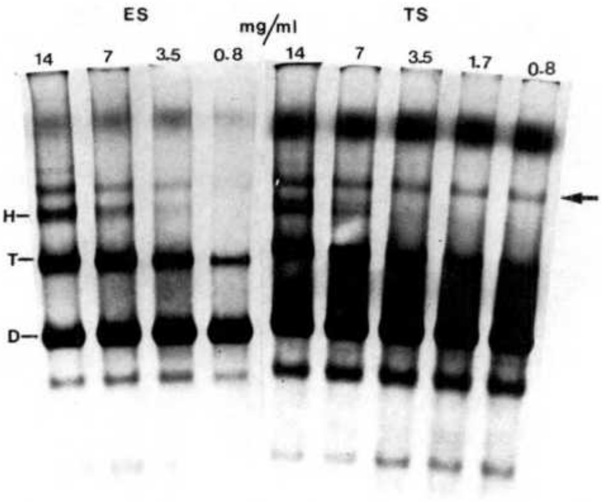

Fig 11. Self-association of spectrin from E.S. (hemolytic HE), and her son T.S. (poikilocytic HE). For details, see legend for Fig 10.

range of concentrations. Crude spectrin extracts from T.S. contain greater than normal amounts of nonspectrin protein, characteristic of spectrin extracts from patients with red cell fragmentation and hemolysis, and include a protein band migrating near spectrin hexamer (arrows). T.S. spectrin also shows smearing of protein between dimer and tetramer; the smear consists largely of spectrin as shown by electrophoresis of the nondenaturing gel into SDS/PAGE in the second dimension (Fig 12). Figure 12 also demonstrates nonspectrin proteins in the crude extract, including a 22 kd peptide (arrow), identified as band 8 (glutathione S transferase)[24] which migrates with the spectrin smear between dimer and tetramer on nondenaturing gels but which separates from spectrin in SDS. No specific interaction between band 8 and the patient's spectrin could be detected by sucrose density gradients of crude spectrin extracts (data not shown).

Quantitative assessment of spectrin oligomer formation in the R and S families is shown in Figs 13 and 14. In Fig 13, the mole fraction of spectrin dimer and of tetramer and higher oligomers is shown for spectrin from family R incubated as described for Fig 9. The initials of family members are again arranged in order of decreasing expression of hematologic disease. In Fig 14, the mole fractions of dimer and tetramer are shown for E.S. and T.S. over the range of spectrin concentrations described in Fig 11; these are compared with a normal control curve derived from a large number of subjects.[19]

It is evident from Figs 13 and 14 that the mole fraction of dimer is elevated and oligomers are decreased in spectrin from all HE/HPP subjects at low spectrin concentrations, and that these differences are not only maintained but are amplified at high concentrations of spectrin; this is important because the spectrin concentration at the membrane surface probably exceeds 100 to 200 mg/mL.[19] These data also show that the degree of impairment of spectrin self-association parallels the hematologic expression of HE and HPP.

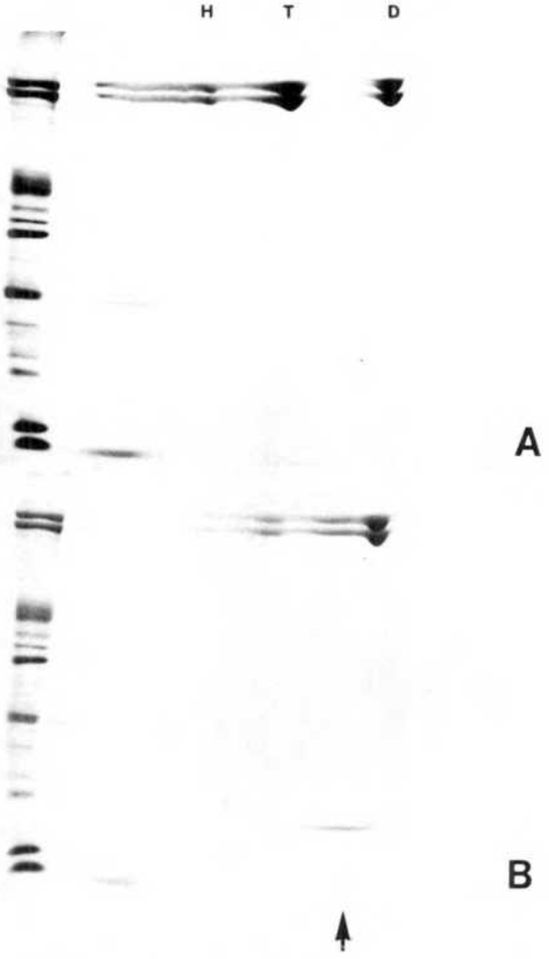

Fig 12. Nondenaturing 2% to 4% acrylamide gels of spectrin from (A) a normal control and (B) a subject which has been electrophoresed in the second dimension into sodium dodecyl sulfate polyacrylamide gel electrophoresis using a 10% to 15% acrylamide gradient. D, dimer; T, tetramer; H, hexamer. Arrow, band 8 (glutathione-s-transferase).

DISCUSSION

HE appears to be a heterogeneous disease caused by deficiencies or abnormalities in several components of the membrane skeleton including, to date, the α and β subunits of spectrin[10–13,15,25,31] and protein 4.1.[26,27] All HE kindreds reported with abnormal spectrin have also evidenced abnormal spectrin self-association, which is thought to be responsible, at least in part, for the shape change, decreased mechanical fragility,[15] and shortened survival observed. We have described here two families with HE whose spectrin demonstrates an abnormal α I domain (α I T80) detected by its increased susceptibility to tryptic cleavage. Normal α I T80 is highly resistant to further tryptic cleavage under the mild digestion conditions used, yielding small (and variable) amounts of a 74 kd peptide and a 50 kd peptide, as well as lower mol wt fragments (S. Marchesi and J. Letsinger, unpublished observations). The α I 74 kd and 50 kd peptides produced from normal spectrin have been shown by Speicher

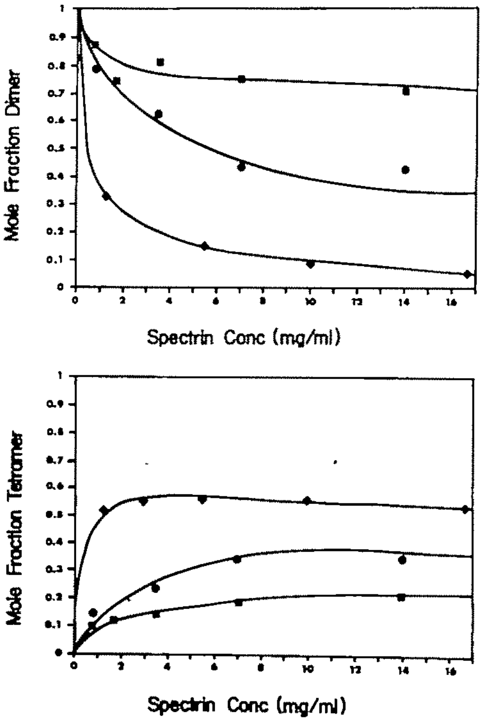

Fig 14. Quantitation of spectrin dimer and tetramer from T.S. (■), and E.S. (●) by pyridine elution of Coomassie blue dye from the native gels shown in Fig 11. See legend for Fig 9 for experimental details. The control curve (♦) is a composite of studies on normal individuals as previously reported.[18]

et al[28] to result from cleavage of peptide from the N terminus of the α subunit. The spectrin of HPP patients is characterized by an α I T80 domain which is readily cleaved under the same conditions to a 50 kd peptide[10] (or 46 kd peptide[11-13]) presumably due to altered conformation of the 50 kd cleavage site leaving little, if any, residual intact α I T80 peptide. By contrast, a smaller fraction of the α subunit is abnormal in patients with HE; whereas two-dimensional peptide maps of all affected individuals demonstrate cleavage of α I T80 to α I T50, a variable amount of unaltered α I T80 remains as shown above and by others.[13]

The cleavage of α I T80 to α I T74, although frequently increased in this population, does not correlate quantitatively with hematologic expression of HE (Fig 6). It should be noted, however, that other investigators have determined the α I 80 → 74 cleavage to be typical of a subpopulation of patients with HPP and HE.[11-13] The differences between their results and ours may be due to methodology, in particular due to characteristics of the digestion conditions including pH and ionic strength, which are known to affect specific cleavage sites (W. Knowles and J. Morrow, unpublished observations).

The most likely interpretation of our observations is that an altered amino acid sequence within the α I domain of HE and HPP spectrin produces conformational changes in neighboring portions of the peptide, resulting in increased exposure of the (normal) tryptic cleavage site at lysine 252,[28] producing an increased quantity of the 50 kd α I peptide, and possibly increasing cleavage at arginine 39 to produce α I T74. The sequence data suggest that both (normal) 50 kd and 74 kd peptides extend to the same COOH terminal site as the intact α I 80 kd.[28] The 50 kd peptide that appears in digests of HE and HPP spectrin is thought to be identical to the normal 50 kd cleavage product, based on its isoelectric point, monoclonal antibody studies, and I^{125} limit peptide mapping which shows only normal peptides of α I 80 kd.

The presumptive alteration in α I primary structure and resultant conformational change is thought to be responsible for the abnormal spectrin–spectrin interactions observed in patients with HE (and HPP) because the α I domain is known to associate specifically with spectrin dimers to promote oligomer formation.[14] Impairment of spectrin self-association has frequently been reported in HPP and HE, expressed either as increased percentage of dimer in crude extracts at 4 °C,[11-13,15,29,30] or as inability to form tetramers and oligomers after incubation at 30 °C over a range of concentrations.[10] Oligomer formation by spectrin from HE subjects in the two families reported here was reduced in all cases; however, the degree of impairment varied from slight in the patients with mild nonhemolytic HE to severe in the case of patient T.S. with poikilocytic hemolytic anemia, approaching our early findings in HPP.[10] As shown in Figs 6, 13, and 14, the severity of clinical expression of HE in members of the kindreds described is proportional to the fractional quantity of α I T80 with altered conformation as well as to the degree that oligomer formation is reduced.

Another possible interpretation of our observations is that the abnormal segment of spectrin is located in the β 1 domain and, because of its interaction with the α I domain, changes in conformation of α I occur which result in an altered tryptic cleavage pattern. However, we have previously demonstrated[10] that tryptic digestion of HPP spectrin which has been denatured and refolded for 60 seconds produces only α I T50 and α I T21 peptides, whereas normal spectrin generates only α I T80. Because the denaturing conditions used results in dissociation of α and β subunits, and because the refolding period was very short, it seems unlikely that the β subunit is responsible for the altered digestion of the α I domain.

Dhermy et al[31] have reported a spectrin β chain variant in a family with elliptocytosis associated with defective self-association of spectrin dimer. No abnormality of the β 1 domain of spectrin from families R and S was seen on SDS-PAGE of intact spectrin nor on two-dimensional maps of tryptic and NTCB digests (data not shown); however, this does not rule out the possibility of an abnormal β 1.

The increases in apparent mol wt of the variant α II and α III domains may be due to insertion of 4 kd or to an amino acid substitution which affects the sites of tryptic cleavage for both domains. Available data on the α II variants do not support these mechanisms for the α II polymorphism (W. Knowles and D. Speicher, unpublished observations). Alternatively, single amino acid substitutions may affect conformation, changing SDS-binding properties and migration on SDS/PAGE, in addition to altering isoelectric point. No information yet shows how expression of the abnormal α I T80 may be modulated by the variant α II and α III domain peptides observed in family S. The α II variants, which are seen frequently in blacks in our studies, confer no observable effect on erythrocyte membrane stability when present alone, but their effect in the setting of an abnormal α I domain is unknown. The α III variant has been seen in three families in the setting of HE and HPP and with α II variants; nothing is known about its effect on the expression of the abnormal α I T80. The only other subject with the α III variant observed to date had HS but an otherwise normal spectrin tryptic digest.

Although HPP appears to be closely related to HE based on family studies, its occurrence within a particular kindred is not predictable. Mentzer et al[15] conclude from a study of two families that HPP results from compound heterozygosity for HE and a nonelliptocytic carrier state characterized by red cell ghosts with increased mechanical fragility. Lawler et al[13] suggest that HPP red cells contain more of a particular abnormal spectrin than HE cells. There may be multiple alleles coding for the spectrin α subunit, as in the α thalassemia syndromes, and with similar consequences. Thus, if members of a family with HE were to have 1, 2, 3, or 4 abnormal alleles coding for the α subunit, a corresponding proportion of spectrin would contain the abnormal α I 80K. As the number of affected alleles increased, the hematologic expression would range from mild HE to severe poikilocytic hemolytic anemia. This concept is particularly attractive because of the multiple α subunit mutations observed in spectrin from the same individual. Thus, variants in α I, α II, and α III seen in the spectrin of one individual need not all occur on the same molecule in the four-allele model. It may be that the α II or α III variants have no pathophysiologic effect if present alone on an α subunit, but if present on the same α subunit as the α I T80 → 50 mutation, they may interact with and modulate expression of hemolytic disease.

Chronic B-Lymphocytic Leukemia Cells Proliferate and Differentiate Following Exposure to Interferon In Vitro

By Leif Östlund, Stefan Einhorn, Karl-Henric Robèrt, Gunnar Juliusson, and Peter Biberfeld

The ability of interferon (IFN) to induce proliferation and differentiation in malignant B cells from 29 patients with chronic lymphocytic leukemia (CLL) and in lymphoid cells from 11 healthy donors was investigated. IFN induced transformation and plasmacytoid differentiation in B cells from 19 of 29 CLL patients. The transformed cells belonged to the malignant clone as indicated by the immunoglobulin (Ig) light chain restriction. Cells exposed to IFN expressed intracellular Ig to a varying degree, which was correlated to the level of plasmacytoid differentiation. IFN gave rise to proliferative responses in cells from three patients. Cytogenetic studies on lymphoid cells from one patient showed that proliferation occurred in the malignant B cells. Induction of proliferation and differentiation was observed with various α-IFN and γ-IFN preparations, as well as with a completely pure β-IFN, showing that IFN and not contaminants in the preparations were responsible for the observed effects. Maximal transformation and proliferation usually occurred after four days of incubation at an IFN concentration of 500 to 5,000 U/mL. The ability of IFN to induce differentiation in CLL cells may be of importance for the reported antitumoral effects observed in some B cell malignancies during IFN therapy.

© 1986 by Grune & Stratton, Inc.

INTERFERON (IFN) can induce remissions in leukemias[1-3] and other malignancies.[4,5] However, the mechanism behind these antitumor effects is not known. It has been suggested that IFN may act indirectly, by stimulating functions of the immune system.[6] IFN may also act directly, by inhibiting cell multiplication,[7,8] and/or by induction of differentiation in the malignant cells.[9,10] Because differentiation blockage is a basic defect leading to malignant clonal expansion, an abrogation of this blockage may lead to a transformation of malignant cells into more benign phenotypes. We now show that α-IFN, β-IFN and γ-IFN can induce blast transformation and differentiation of varying degrees in leukemic cells from ~65% (19 of 29) of patients with CLL as well as proliferation in 3 of 29 patients.

MATERIALS AND METHODS

Patients

Twenty-nine patients with a diagnosis of chronic B lymphocytic leukemia were investigated. Hematological findings, clinical data and Rai stage[11] at the time of sampling are presented in Table 1. Diagnosis was established by morphology and by immunological studies on peripheral blood, bone marrow, and lymph node samples according to the Kiel Lymphoma Study Group.[12] Most patients (22 of 29) had not received any previous treatment for their disease.

IFN and Mitogen Preparations

Natural α-IFN (α-IFN) provided by Dr D. Secher, was prepared from Sendai virus-induced human Namalwa cells and was purified with an anti-IFN antibody affinity system.[13] The specific activity of this preparation was 2 × 10^8 U/1 mg protein, and the purity was ~90%.

Recombinant α_2-IFN (R. α_2-IFN) derived from *E coli*, with a specific activity of 3.2 × 10^8 U/1 mg protein was provided by Dr G. R. Adolf, Ernst-Boehringer-Institut, Vienna. The purity of this preparation was >99%.

Recombinant γ-IFN (R. γ-IFN) with a specific activity of 3.5 × 10^7 U/1 mg protein was provided by Dr G. R. Adolf, Ernst-Boehringer-Institut.

Pure β-IFN was provided by Dr E. Knight, Central Research and Development Department E. I. du Pont de Nemours and Co. This IFN preparation, with a specific activity of ~2 × 10^8 IFN U/1 mg protein, was produced, purified, and characterized as previously described.[14] According to amino acid analysis, it contained no polypeptides other than IFN.[15]

The antiviral activities of the IFN preparations were tested by an assay measuring cytopathogenic effect of vesicular stomatitis virus in fibroblasts.[16] The various IFN preparations were titrated against international standard preparations.

Mock α-IFN was provided by Dr K. Cantell (Finnish Red Cross, Helsinki). It was prepared from buffy coat suspensions of leucocytes using normal allantoic fluid as inducer.[17] It contained no measurable antiviral activity at the concentrations used.

Lipopolysaccharide (LPS), derived from *E coli* (055:B5), was provided by Professor Tord Holme, Department of Bacteriology, Karolinska Institute, Stockholm; it was used at a final concentration of 100 μg/mL.

Phytohemagglutinin M (PHA) (DIFCO Laboratories, Detroit). The substance was rehydrated by adding 5 mL of sterile distilled water, and the solution was used at a final dilution of 1:67.

Cells and Culture Conditions

Heparinized peripheral blood was centrifuged on a Ficoll-Isopaque density gradient.[18] The interface was collected and washed three times in modified Eagle's medium (MEM) (Flow Lab, Irvine, England) supplemented with 10% heat-inactivated human AB serum and antibiotics (penicillin 50 μg/mL, streptomycin 50 μg/mL). A sample of the cells was stained with crystal violet solution and counted. A final concentration of 2 × 10^6 lymphocytes per milliliter was used. Ten-milliliter cultures for studies on cellular morphology and cellular immunoglobulin content were set up in 50-mL plastic flasks (Falcon 3031, Oxnard, Calif). For measurement of proliferative response, 0.2-mL microcultures were set up in round-bottomed 96-well plates (Flow Lab). Cultures were then incubated for one to six days in a humidified atmosphere with 5% CO_2 at 37 °C. Mitogens and IFN preparations were present throughout the cultures. The cell viability was determined by trypan blue staining. Usually, between 1 and 2 × 10^6 cells per milliliter remained after

four days in culture. With few exceptions, the proportion of dead cells in these cultures varied between 1% and 5%.

Assay for DNA-Synthesis

Twenty-four hours before harvesting, 1.0 μCi of ^{3}H-thymidine with a specific activity of 5 Ci/mmol (TRA 120, Radiochemical Centre, Amersham, England) was added to each culture. Harvesting was performed with a Skatron Harvesting Machine (Lierbyen, Norway) and the radioactivity was measured with a scintillation spectrophotometer (Packard Instrument Company, Inc, Downers Grove, Ill). These assays were performed in triplicate. The variation within triplicates was usually <15%. Induction of proliferation was defined as an increase in counts per minute (cpm) of >100% above medium control as well as a numerical net increase of $\geq 2 \times 10^3$ cpm.

Measurement of Morphological Changes

If not otherwise stated, morphological changes were evaluated after four days of culture. Approximately 1×10^5 cells in 0.1 mL were centrifuged (Cytospin, Shandon Southern, Runcorn, England) for ten minutes onto glass slides, and were then stained with May-Grünewald-Giemsa (MGG) and mounted with cover glass in Eukitt. The samples were examined "blindly" in light microscope. Because there was a considerable variation in the size of primary cells as well as cells cultured in medium without stimulants, we classified the cells into four groups as follows[19]: SL, small lymphocytes (<12 μm); SB, large lymphocytes and small blasts (12 to 15 μm); MB, medium blasts (15 to 19 μm); and LB, large blasts (>19 μm). At least 200 cells were counted and the percentage of each lymphocyte subgroup was determined. The data were scored as follows: SB, 1 point; MB, 2 points; LB, 3 points. To allow a statistical evaluation of the morphological transformation, a Lymphoblast Transformation Score (LTS) formula was created: LTS = (SB% × 1) + (MB% × 2) + (LB% × 3). A net increase in the LTS by 20 points or more was arbitrarily designated as positive morphological transformation. This LTS index correlated well with the subjective impression of transformation in individual clones.

Immunofluorescence and Peroxidase–antiperoxidase (PAP) Technique

After 5 days in culture, the cells were washed three times in balanced salt solution (BSS) and were then incubated at 37 °C for one hour in BSS. Cytospin preparations were fixed in acetone for ten minutes at 4 °C. Surface immunoglobulin (Ig) was demonstrated by immunofluorescence after incubation with fluorescein isothiocyanate (FITC) conjugated F(ab′)$_2$ rabbit antibodies to human Ig of light κ and λ chains (Kallestads Lab, Chaska, Minn).[20] Intracellular Ig (κ and λ light chains) was demonstrated by the PAP-technique[21,22] with suitable monoclonal antibodies.

Chromosome Analysis

Cytogenetic analysis was performed on cells from patient 3, cultured with and without 5,000 U/mL of α-IFN for four days. After treatment with colchicine and a hypotonic potassium chloride solution, the cells were fixed in methanol/acetic acid and were then air-dried as previously described.[23] Q-banded metaphases suitable for chromosome analyses were photographed in a Zeiss fluorescent microscope and were analyzed by conventional karyotyping from paper copies.[24]

Statistical Analyses

Statistical differences were evaluated using Student's *t* test (number of patients > 20) or the Wilcoxon matched-pairs signed-ranks test (number of patients < 20). Pearson correlation coefficients were used to evaluate correlations.

RESULTS

Induction of Blast Transformation

α-IFN at the concentration 5,000 U/mL transformed the lymphocytes to blasts in cultures from 19 of 29 patients (LTS increase of more than 20 points) (Fig 1). By means of a concentration of 50 U/mL, blast transformation was observed in lymphoid cells from 10 of 25 patients (Table 2, showing data from the first tests performed). The mean increase in LTS using α-IFN was statistically significant for both IFN concentrations ($P < .001$). Five thousand IFN U/mL was more efficient in inducing blast transformation than was 50 U/mL ($P < .05$). There was also a good correlation in induction of transformation between these two IFN concentrations ($P < .001$). LPS induced transformation in cells from 18 of 29 patients (Table 2). There was a close correlation between IFN-induced and LPS-induced transformation (50 and 5,000 U/mL; $P < .001$). Lymphoid cells from four responding patients were tested on four different occasions within one year. Lymphocytes from three of these patients responded to IFN by blast transformation at all times. In cells from one patient, transformation occurred on two occasions, whereas no effects were observed in the other two instances (data not shown). Cells from four patients not responsive to IFN were also tested at several occasions; no responses were seen at any test (data not shown). These findings indicate that responsiveness to IFN, with some

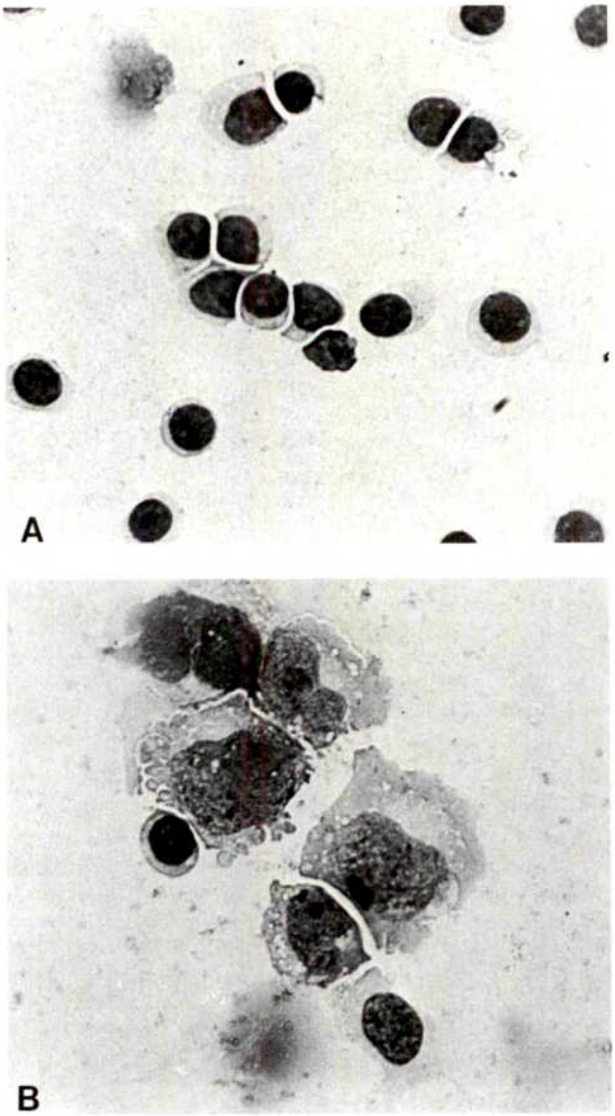

Fig 1. Lymphoid cells from patient 3 cultured for four days: (A) without IFN, showing a homogeneous picture of small regular lymphocytes; and (B) with α-IFN 5,000 U/mL, showing a varying degree of morphological transformation into blasts and plasmacytoid cells.

Controls	9 ± 3	ND	12 ± 3	15 ± 14

Data are expressed in Lymphoblast Transformation Score (LTS); mean ± SE for patients and controls are shown.

LPS, lipopolysaccharide; ND, not done.

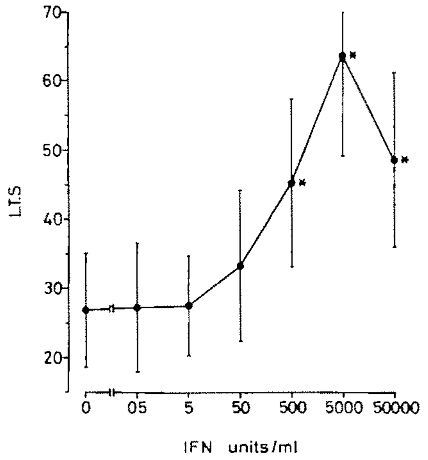

Fig 2. Lymphoblast transformation in malignant B cells after four days of incubation in varying concentrations of α-IFN. Means ± SE from eight patients. Data are expressed in Lymphoblast Transformation Score (LTS); *$P < .05$.

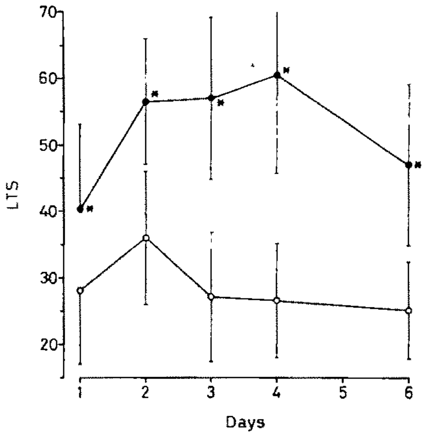

Fig 3. Lymphoblast transformation in malignant B cells after exposure to medium without (O—O) or with 5,000 U/mL of α-IFN (●—●) for one to six days. Means ± SE from seven patients. Data are expressed in Lymphoblast Transformation Score (LTS); *$P < .05$.

exceptions, is a fairly constant characteristic of a malignant clone.

Lymphocytes from 11 healthy donors showed no major increase in blast transformation after four days of culture with 5,000 U/mL of α-IFN (Table 2). Cells from one donor responded to LPS with blast transformation.

Surface immunofluorescence (κ and λ Ig chains) was studied in IFN-responsive cells from four patients. Between 95% and 100% of the cells exposed to IFN expressed membrane light chains of one type only, demonstrating that most of the cells undergoing blast transformation were clonal.

Dose of IFN and Lymphoblast Transformation

Lymphoid cells from eight patients were incubated with 0 to 50,000 U/mL of α-IFN for four days. In lymphocytes from six of the patients, IFN induced blast transformation. The maximal transformation was observed at IFN-concentrations of 500 to 50,000 U/mL (Fig 2). Induction of blast transformation was statistically significant for the three highest IFN concentrations used ($P < .05$).

Kinetics of IFN-Induced Lymphoblast Transformation

Lymphoid cells from seven patients were incubated with or without 5,000 U/mL of α-IFN for 1, 2, 3, 4, and 6 days (Fig 3). After one day in culture with α-IFN, the cells showed a significant increase in the degree of blast transformation ($P < .05$). The IFN-induced transformation seemed to be most pronounced after four days in culture (Fig 3).

Differentiation of Transformed Cells Detected With PAP-Staining

In most cases, a proportion (30% to 80%) of IFN-transformed CLL cells showed a plasmacytoid morphology. These cells, included in the SB group and MB group, were characterized by a relatively dense chromatin and by smaller nuclei than those of the other transformed cells. The plasmacytoid level of differentiation of malignant cells was confirmed by intracellular immunoglobulin κ- and λ-light chain staining. An increased proportion of IFN-transformed cells displayed intracellular immunoglobulin of the same light chain isotype as that of the surface membrane Ig phenotype (Table 3).

Induction of Proliferation

In lymphoid cells from 3 of the 29 patients tested (patients 3, 9, and 27) 5,000 U/mL of α-IFN increased the uptake of ^{3}H-thymidine after four days in culture (Table 4, data from the first tests done). The proliferative responses to IFN in cells from these patients were confirmed in repeated experiments during the course of the disease. Cells from these three patients were also responsive to LPS, and cells from 93% (26

Table 3. Differentiation in Cells From Patients 1 and 3

		Surface Light Chains				Intracellular Light Chains							
	Cultured	κ		λ		κ				λ			
Patient	With:	o	+	o	+	o	+	++	+++	o	+	++	+++

LPS, lipopolysaccharide; PHA, phytohemagglutinin; ND, not done.

of 28) of all patients were responsive to phytohemagglutinin (PHA) (Table 4).

Lymphoid cells from 11 healthy donors were cultured together with α-IFN. No major increase in ^{3}H-thymidine uptake was observed after exposure of the cells to IFN. Cells from one donor responded to LPS, and lymphoid cells from all donors responded to PHA by proliferating.

Dose of IFN and Proliferation

Lymphoid cells from 9 patients (3 with cells responsive and 6 with cells nonresponsive to 5,000 U/mL of α-IFN) were incubated with 0 to 50,000 U/mL of α-IFN for 4 days (Fig 4). In responsive cells from the three patients, maximal stimulation of proliferation occurred at 500 to 5,000 U/mL of α-IFN. At the highest IFN concentration used (50,000 U/mL), the proliferative response was less pronounced. In nonresponsive cells from the six other patients, none of the IFN concentrations gave rise to a proliferative response.

Kinetics of IFN-induced Proliferation

Lymphoid cells from eight patients (3 with cells responsive and 5 with cells nonresponsive to 5,000 U/mL in 4-day cultures) were incubated for 1, 2, 3, 4, and 6 days in the presence or absence of 5,000 U/mL of α-IFN (Fig 5). In responsive cells from the three patients, maximal proliferation occurred after three to four days of incubation. In nonresponding cells from the five other patients, no IFN-induced proliferation was observed on either 1, 2, 3, 4, or 6 days of incubation.

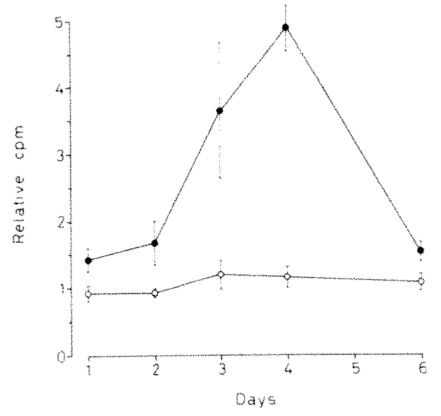

Fig 4. Incorporation of ^{3}H-thymidine in IFN-responsive cells from three patients (●—●) and in cells not responsive to IFN from six patients (○—○) (means ± SE). Cells were cultured in the absence or presence of 5,000 U/mL of α-IFN for one to six days. Relative cpm = cpm with IFN divided by cpm with medium only.

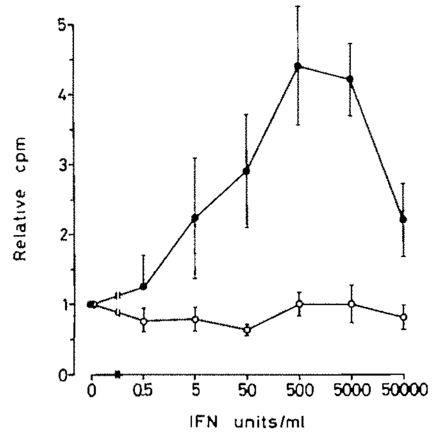

Fig 5. **Incorporation of ^{3}H-thymidine in IFN-responsive cells from three patients (●—●) and in cells not responsive to IFN from six patients (○—○) (mean ± SE). Cells were cultured for four days with different concentrations of α-IFN. Relative cpm = cpm with IFN divided by cpm with medium only.**

Proliferative Responses to Combinations of IFN, LPS, and PHA

To study the influence of IFN on LPS-induced and PHA-induced proliferation, cells from eight patients were incubated with LPS or PHA in the absence or presence of α-IFN (Table 5). Lymphoid cells from three patients responded to IFN by proliferating. The addition of both IFN and LPS to cell cultures from these patients did not give rise to an additive effect on proliferation. With the highest IFN concentrations used, there was a tendency toward an inhibition of the proliferative response (Table 5). In the cell cultures that did not respond to IFN alone by proliferating, addition of IFN had no major influence on the LPS-induced proliferative responses. Addition of IFN to PHA-stimulated cultures caused an inhibition of the proliferative responses (Table 5).

Table 5. Incorporation of ^{3}H-thymidine (cpm × 10^{-3}) in Lymphoid Cells

Substance (U/mL)	Response to IFN (n = 3)	No Response to IFN (n = 5)
Medium	2.0 ± 0.8	2.7 ± 0.9
IFN (50)	6.9 ± 3.1	4.0 ± 1.6
IFN (5,000)	20.3 ± 14.5	3.2 ± 1.4
IFN (50,000)	20.3 ± 10.8	3.8 ± 2.0
LPS	22.1 ± 16.0	10.7 ± 3.3
LPS + IFN (50)	34.5 ± 19.9	7.9 ± 3.0
LPS + IFN (5,000)	17.6 ± 11.3	10.0 ± 3.4
LPS + IFN (50,000)	11.7 ± 4.9	8.3 ± 3.1
PHA	88.7 ± 29.9	52.1 ± 31.0
PHA + IFN (50)	84.0 ± 31.2	60.1 ± 28.0
PHA + IFN (5,000)	54.4 ± 22.0	35.6 ± 18.5
PHA + IFN (50,000)	37.6 ± 18.0	25.7 ± 15.9

Cells were cultured for four days in vitro with α-IFN (50, 5,000, or 50,000 U/mL) and/or LPS or PHA. Data are presented as mean ± SE. Cells from all patients responded to LPS and PHA. Cells from three of the patients responded to IFN.

LPS, lipopolysaccharide; PHA, phytohemagglutinin.

Table 6. Transformation in Lymphoid Cells From Seven Patients

Patient	Medium	Mock α-IFN	α-IFN	R.α_2-IFN	Pure β-IFN	R.γ-IFN
3a	31	27	62	58	66	ND
3b	27	19	49	ND	75	ND
3c	6	ND	29	30	75	ND

27b	10	ND	34	ND	36	ND
29	12	ND	46	55	ND	ND

Cells were cultured for four days in vitro with 5,000 U/mL of different IFN preparations. Data are collected from several experiments (a, b, . . .) and expressed in Lymphoblast Transformation Score (LTS).

ND, not done.

Cytogenetic Analysis on Induced Cells

Chromosome analysis was carried out in cells from patient 3. Fifteen metaphases from the cell culture stimulated with α-IFN (5,000 U/mL) and nine metaphases in LPS-stimulated cells were studied. In each of these cell cultures, three metaphases had an identical chromosomal aberration. The aberrant chromosome was a no. 11 with the long arm deleted at band q22, as previously reported (patient 117 in ref. 23). The remaining metaphases all had a normal 46,XY karyotype. Unstimulated cell cultures yielded no evaluable metaphases.

Studies Using α-IFN, β-IFN and γ-IFN Preparations

Different IFN preparations of varying purities were tested for their capacity to induce proliferation and transformation in CLL cells. Lymphoid cells from the patients were incubated with pure β-IFN, natural α-IFN, recombinant α_2-IFN, recombinant γ-IFN, and mock α-IFN (Tables 6 and 7). The results showed that all IFN preparations, including the pure β-IFN, induced proliferation and blast transformation in the malignant B lymphocytes, whereas the mock-IFN preparation had no effect. There seemed to be no major difference in the relative capacity of α-IFN, β-IFN, and γ-IFN to induce proliferation and blast transformation (Tables 6 and 7). Neither did lymphoid cells that showed no response to α-IFN by proliferation and/or blast transformation show any response to β-IFN or γ-IFN.

Table 7. Proliferative Responses in Lymphoid Cells From Patients 3 and 9

Patient	Mock α-IFN	α-IFN	R.α_2-IFN	Pure β-IFN	R.γ-IFN
3a	ND	12.1	ND	ND	3.9
3b	ND	14.1	ND	ND	ND
3c	0.9	4.7	3.0	ND	ND
3d	0.7	3.5	2.1	3.7	ND
9	ND	2.8	ND	3.5	ND

Cells were cultured for four days with 5,000 U/mL of different IFN preparations. Data are collected from several experiments (a, b, . . .) Incorporation of ^{3}H-thymidine is presented as relative cpm = cpm with IFN divided by cpm with medium only.

ND, not done.

Correlation Between Clinical Data and Transformation/Proliferation

No correlations between α-IFN–induced transformation/differentiation and clinical parameters, such as hematological data or clinical stage were found. IFN-induced proliferation was detected in three untreated males with the diagnosis immunocytoma (IC) (patients 3, 9, and 27), with moderate increases in lymphocyte counts and Rai stages 0 through 1. Patients with high lymphocyte counts showed lower responses to PHA stimulation ($P < .05$).

DISCUSSION

An enhancing effect of IFN on mitogen-induced differentiation of normal and malignant B cells has previously been reported.[9,10,25] We now demonstrate that leukemic cells from a large number of patients with chronic B lymphocytic malignancies respond to IFN in vitro with blast transformation and with differentiation to plasmacytoid cells without the addition of other stimulatory agents. Membrane immunofluorescence studies showed that most blast transformed cells were monoclonal B cells. Studies of morphological changes as well as the induction of intracellular Ig light chains showed that varying proportions of the leukemic cells transformed into plasmacytoid levels of differentiation following exposure to IFN.

The observed effects were not due to contaminants in the IFN preparation used, since the results were similar using several IFN preparations, one of which was completely pure. Maximal effects were usually observed after four days in culture and at IFN concentrations of 500 to 5,000 U/mL. These IFN concentrations are found in the serum of patients receiving IFN by the intravenous route.

In most of the patients, blast transformation was not accompanied by a measurable induction of proliferation, as tested at different times using a range of IFN concentrations (Figs 4 and 5). This suggests that DNA synthesis is not required for IFN-induced blast transformation to occur. In cells from three IC patients, however, IFN induced a proliferative response, measured by an increase in the ^{3}H-thymidine uptake. The clonality of the proliferating cells was evidenced by the finding that in one case metaphase cells contained a clonal chromosomal aberration. Stimulation of tumor growth in vitro by IFN has previously been suggested by others.[26,27] However, IFN is generally known as an inhibitor of cell proliferation.[5,7,8]

The individual response patterns to IFN-induced proliferation and transformation were usually reproduced in repeated experiments during the course of the disease. It has previously been demonstrated that a battery of B cell mitogens can be used to classify leukemic lymphocytes into various subsets with different functional and clinical characteristics.[28,29] The mechanism behind and the physiological significance of the IFN-induced transformation and proliferation is poorly understood. However, we have recently studied the effect of IFN on enriched B lymphocytes from healthy donors. These data suggest that IFN can also stimulate certain normal B cell subsets and that stimulation of proliferation is not T cell dependent.[30]

In another recent study, we have shown that leukemic B cell clones that respond to IFN by blast transformation also express enhanced levels of the enzyme 2′-5′oligoadenylate synthetase on exposure to IFN, whereas this enzyme was not induced in CLL clones that did not respond to IFN by blast transformation. The observed correlation between induction of 2′-5′oligoadenylate synthetase and blast transformation, indicates that some CLL clones do not differentiate following exposure to IFN because the cells have a resistance to the action of IFN.[31]

IFN has been shown to induce remissions in some patients with B cell malignancies. The mechanisms behind these effects are not known. A previous investigation in tumor patients showed that of several tested immunological functions only natural killer cell activity increased during α-IFN therapy.[6] However, the increments of natural killer cell activity were not correlated to the response to treatment in myeloma patients.[32] IFN-induced differentiation, by means of an abrogation of the maturational arrest in tumor cells, may play an important role in the antitumoral action of IFN in leukemias. Furthermore, studies on the effect of IFN on leukemic cells in vitro may constitute an experimental system for the identification of patients in whom antitumor effects of IFN treatment can be expected.

ACKNOWLEDGMENT

The excellent technical assistance of Elisabet Anderbring, Birgitta Ånséhn, Marianne Ekman, and Ann-Christine Melén is gratefully acknowledged. We thank Drs Ernest Knight Jr, David Secher, Otto Adolf, and Kari Cantell for providing the Interferon preparations used and Bo Nilsson, BSc, for help with the statistical analyses.

HTLV-III Infection After Bone Marrow Transplantation

By Joseph H. Antin, Brian R. Smith, Bruce M. Ewenstein, Robert J. Arceci, Jeffrey M. Lipton, Peter L. Page, and Joel M. Rappeport

We prospectively documented the development of a fatal, secondarily acquired severe immunodeficiency in a 19-year-old man who underwent uncomplicated bone marrow transplantation. He had no graft *v* host disease (GVHD) and had normal recovery of his immune system as determined by lymphocyte phenotyping, mitogenic responses of his peripheral blood lymphocytes, and his ability to secrete immunoglobulin. This alteration in immunity was associated with the acquisition of antibody to HTLV-III. His only risk factor for the development of HTLV-III infection was the transfusions he had received during the transplant and recovery period. Two of his 54 transfusions were from an asymptomatic individual at high risk for acquired immunodeficiency syndrome (AIDS), who was subsequently found to be seropositive for anti-HTLV-III and from whom HTLV-III was isolated. The loss of immunocompetence in patients without chronic GVHD disease is unusual, and our data support the view that this patient's immunodeficiency was due to HTLV-III. When bone marrow transplant recipients without chronic GVHD develop late opportunistic infections, consideration should be given to transfusion-associated AIDS.

© 1986 by Grune & Stratton, Inc.

THE ACQUIRED immunodeficiency syndrome (AIDS) is a disease which is thought to be due to a T lymphotropic retrovirus, HTLV-III.[1] It is most often seen in homosexual or bisexual males, intravenous drug abusers, severe hemophiliacs using lyophilized clotting factor concentrates, and individuals from underdeveloped countries in whom the disease is prevalent in the heterosexual population. Occasionally, it occurs in recipients of blood product transfusions.[2-5] Bone marrow transplant recipients receive frequent transfusions, but evidence of HTLV-III infection has not been reported in these patients. Following transplantation, these patients often have persistent defects of cellular and humoral immunity; however, in the absence of chronic graft *v* host disease (GVHD) late opportunistic infections and the loss of reestablished immune function are uncommon.[6-13] We had the opportunity to observe prospectively the recovery and subsequent loss of immune function in a bone marrow transplant patient who was exposed to blood from an individual who is at high risk for AIDS, who was shown to be seropositive for anti-HTLV-III antibody, and from whom HTLV-III was subsequently isolated. The loss of immune function was associated with the development of clinical and laboratory abnormalities that support the diagnosis of HTLV-III infection and associated immunodeficiency.

MATERIALS AND METHODS

All studies were done in accordance with institutional review board guidelines.

Phenotype analysis. Peripheral blood mononuclear cells were obtained by Ficoll-Paque (Pharmacia, Piscataway, NJ) density gradient centrifugation of heparinized peripheral blood. Monocytes were depleted by incubation with carbonyl-iron (Technicon, Tarrytown, NY), Ficoll-Paque centrifugation, and plastic adherence. The surface phenotypes were established by incubating the cells for 30 minutes at 4 °C with the fluoresceinated monoclonal antibodies Leu-4, Leu-2, and Leu-3 (Becton Dickinson, Mountain View, Calif) and were washed three times with phosphate-buffered saline (PBS). They were analyzed on a FACS Analyzer (Becton Dickinson, Sunnyvale, Calif).

Lectin-stimulated proliferation. Peripheral blood was collected in preservative-free heparin (100 U/mL) and the mononuclear cells were separated on a Ficoll-Paque gradient. The mononuclear cells were washed twice in Hanks' balanced salt solution (HBSS) (Grand Island Biological Co, Grand Island, NY) and resuspended in RPMI 1640 (GIBCO) with 5% heated inactivated human AB serum, L-glutamine, penicillin, streptomycin, and mycostatin. Blastogenic responses to phytohemagglutinin (PHA) and concanavalin A (Con A) (Difco Laboratories, Detroit) were determined in triplicate in a microtiter system with 10^5 cells per well. Optimal concentrations of mitogens were determined in preliminary experiments on normal donors for each batch of mitogen and, in the case of PHA, three concentrations of PHA over a tenfold range were assessed for each separate patient determination to assure study at maximum response. Median concentrations required were 2 μg/mL of PHA and 3 μg/mL of Con A. Cells were incubated at 37 °C in a 5% CO_2 incubator and were pulsed on day 3 for 18 hours with 1.0 mCi/mL ^{3}H-thymidine (New England Nuclear, Boston, Mass). Cultures were harvested on an automatic microtiter harvester (MASH II; M.A. Bioproducts, Bethesda, Md), and incorporated radioactivity was determined in a scintillation counter. PHA and Con A stimulation indices are determined by dividing the observed counts per minute (cpm) by the background control values; in our laboratory, normal stimulation indices are >20.

Screening of blood donors. Blood donation numbers of all blood products transfused to the patient were provided to the regional blood collecting facility. Donors were contacted by the collecting facility and 15 agreed to complete an extensive questionnaire and to be screened with complete blood counts, lymphocyte phenotyping, and anti-HTLV III serology (performed at the Centers for Disease Control).

RESULTS

Case report. A 19-year-old, white man without prior history of homosexuality, drug abuse, bleeding disorder, travel to Haiti, or transfusion was admitted to the Brigham and Women's Hospital in September, 1981 with acute

monocytic leukemia (FAB M5a). Complete remission was achieved with daunorubicin and cytosine arabinoside (ara-C), and he received four cycles of consolidation chemotherapy (daunorubicin, ara-C, and 6-thioguanine). During the period of anti-leukemia chemotherapy, he received 10 units of washed red blood cells (RBC), 3 units of single donor pheresis platelets, but no fresh frozen plasma or granulocyte transfusions.

In April 1982, he underwent allogeneic bone marrow transplantation from his HLA-matched, MLR-nonreactive brother. The patient was prepared for transplantation with ara-C 500 mg/m^2/d for seven days, cyclophosphamide 60 mg/kg/day for two days, and 850 rad single-fraction total body irradiation at a midline dose rate of 5 rad per minute. After transplantation, he received four doses of methotrexate (10 mg/m^2) on days 1, 3, 6, and 11. His course was uncomplicated; he had > 500 granulocytes per microliter at day 34, and developed grade I acute GVHD, which did not require therapy. No chronic GVHD was observed clinically or on skin biopsy. Following his transplant, he received 7 units of washed RBC as well as platelet transfusions from 18 different donors, either as platelet pheresis products or as platelet concentrate (prepared from whole blood donors). He never required granulocyte transfusions or fresh frozen plasma. An arteriovenous shunt (which had been placed prior to transplant for vascular access) was removed on day 240 (month 8, October 1982); during the surgery, he received an additional 2 units of washed RBC and two bags of pooled platelet concentrates from a total of 13 donors. The next year was spent primarily at home, with limited contact with nonhousehold members. He had mild persistent thrombocytopenia after transplant, with platelet counts ranging from 70,000 to 100,000/μL. During this time in vitro lymphocyte function returned to normal (Fig 1) as did immunoglobulin levels, but his absolute lymphocyte count had started to decline. He denied homosexual activity or intravenous drug use.

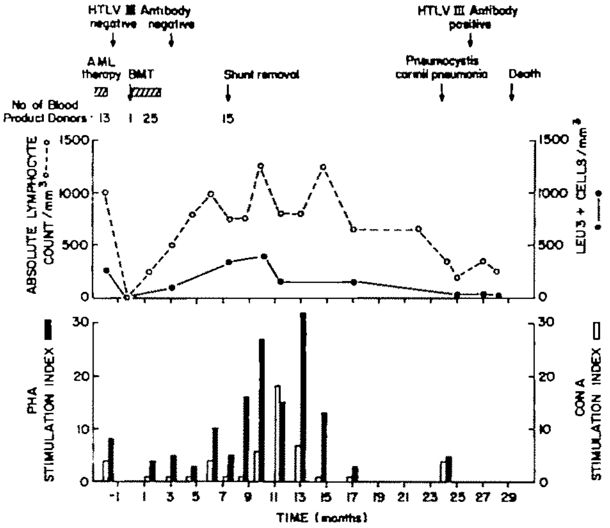

Fig 1. Serial immunologic studies in a patient who developed HTLV-III infection after bone marrow transplantation. There is a progressive improvement in lymphocyte numbers and the mitogenic responsiveness of the patient's lymphocytes to lectins until month 7, ~16 months after the suspected transfusions, when there was a decrease in the numbers of circulating lymphocytes, especially Leu-3+ helper/inducer cells. The reduction in the number of Leu-3+ cells was followed over the next two to four months by a diminution in his blastogenic response to lectins. *P carinii* pneumonia developed ~32 months after the suspected transfusion. In our laboratory, normal stimulation indices are > 20. The hatched areas denote the time periods in which blood products were administered.

On day 680 (month 23, February 1984) he developed a low-grade fever and cough. Over the ensuing two to three weeks, he had slowly progressive shortness of breath; he became hypoxic, and his chest X-ray demonstrated a diffuse interstitial pneumonitis. Open lung biopsy established the diagnosis of *P carinii* pneumonia, and he was successfully treated with intravenous trimethoprim-sulfamethoxazole (TMP-SMX). The TMP-SMX therapy was complicated by the development of severe thrombocytopenia (platelets < 20,000/μL), and therapy was completed with pentamidine. Concomitantly, it was noted that he had developed bilateral cervical lymphadenopathy and severe lymphopenia (200 to 490/μL), and lymphocyte surface phenotyping revealed a marked reduction in Leu-3+ (T4 or "helper/inducer") cells (14/μL), and a "helper/suppressor" (Leu-3/Leu-2) T cell ratio of 0.3. Lymphocyte function testing revealed that mitogenic responsiveness to PHA and Con A was now minimal (Fig 1), and he had no delayed hypersensitivity to intradermal mumps, *Candida*, or tuberculin. Serum immunoelectrophoresis revealed that he had developed a polyclonal increase in IgA (425 mg/dL). Antibody to the Epstein-Barr virus was detected both before transplant and immediately after transplant at 1:640, and it increased to 1:2560 at the onset of the interstitial pneumonia. Cytomegalovirus antibody titer was < 1:8 on both occasions.

After recovery from the pneumonia, he continued to have daily fevers to 101 °F, although no source of infection could be determined. The thrombocytopenia never resolved (range 10,000 to 50,000/μL), although bone marrow aspiration demonstrated adequate numbers of megakaryocytes and showed no evidence of recurrent leukemia. He became severely cachectic, and lost > 20% of his body weight; he did not respond to parenteral nutrition therapy. Over the next three months, he developed recurrent bilateral pneumothoraces, which required virtually constant chest tube drainage. There were no skin lesions consistent with Kaposi's sarcoma. Just prior to his death, he became obtunded and had focal seizures. CAT scan revealed an enhancing lesion in the left frontal cortex, which was thought to be consistent with toxoplasmosis, lymphoma, or abscess. Brain biopsy was refused. He died 850 days after transplantation. Postmortem examination was refused.

HTLV-III. Frozen serum specimens were obtained from March 1982 (immediately prior to the transplant), and day 75 (May 1982, immediately following the transplant) as well as a fresh serum specimen on day 780 (month 25, May 1984). His serum was examined for anti-HTLV-III antibodies by indirect immunofluorescence on an HTLV-III–infected H9 cell line by Essex by an established technique,[14] and he was found to be negative before transplant on day 75 but to be positive on day 780 (Fig 1). The positive test was confirmed by radioimmunoprecipitation (Western blot analysis). The marrow donor had no risk factors for AIDS. He was also seronegative for HBsAg and cytomegalovirus (CMV), and had normal responses to lectin stimulation of his peripheral blood lymphocytes immediately prior to the marrow harvest. Although the marrow donor could not be tested for anti-HTLV-III antibodies, the survey of blood product donors revealed one male, homosexual subject who donated two pheresis platelet products in October and November 1981, both of which were transfused into this patient. At the times of donation, the donor met all of the criteria for normal voluntary blood and platelet pheresis donors. In January 1985, this donor was contacted, and blood was subsequently found to be anti-HTLV-III positive by the Centers for Disease Control; HTLV-III virus was recovered. His complete blood count (CBC) (including absolute lymphocyte count and platelet count) and immunoglobulin levels were normal, but his helper/suppressor ratio was 0.37 (normal 0.9 to 3.5). At the time of writing, he remains asymptomatic.

DISCUSSION

Although the recovery of immune function after bone marrow transplantation may be prolonged, most patients who do not have chronic GVHD have relatively normal in vitro parameters of immune function by 1 year.[10,11] Once in vitro immune reactivity recovers, it generally persists. Furthermore, patients without chronic GVHD rarely develop *P carinii*, or other opportunistic infections as late (> 1 year) complications of transplantation.[12] At a time when immune function is usually stable, this patient developed severe lymphopenia, loss of Leu-3+ lymphocytes, cutaneous anergy, loss of his in vitro mitogen responsiveness, opportunistic infection, diffuse lymphadenopathy, severe thrombocytopenia, and polyclonal hypergammaglobulinemia (IgA). This discrepancy from the usual course of immunologic reconstitution after marrow grafting suggested that the illness was not due to a late complication of transplantation. The clinical syndrome was consistent with the diagnosis of HTLV-III–associated immunodeficiency or AIDS. Because we perform lymphocyte function studies on our transplant patients during and after transplantation, we were able to document prospectively the timing and course of immunologic recovery and subsequent immunoincompetence which led to his death. It is the loss of his in vitro cellular immune reactivity following recovery that led us to suspect that he had AIDS, rather than the persistent defects in cellular immunity that have been reported after marrow grafting. All of the above observations are consistent with the selective infection of Leu-3+ cells with HTLV-III and the consequent disproportionate loss of helper/inducer cells.

His only known risk factor for the development of HTLV-III infection was the transfusion of 54 blood products that he had received during the leukemia treatment, transplant, and recovery period, 2.5 to 3 years prior to his illness and, in particular, 2 units from an anti-HTLV-III seropositive, homosexual individual transfused 16 months prior to the first demonstrable reduction in Leu3+ cells, and 34 months prior to death. The latency between this transfusion and the development of opportunistic infections is consistent with the incubation period observed in transfusion-associated AIDS.[2] It is unusual to be able to document the probable date of HTLV-III exposure and complement that dating with serial immune function studies. It is notable that the patient was seronegative immediately prior to his transplant. The subsequent development of HTLV-III antibodies suggests continued viremia followed by antibody production when his humoral immune response recovered. On the other hand, viremic but antibody-negative patients have been reported,[15] and it is unknown to what extent his underlying leukemia and chemotherapy might have delayed or prevented the development of antibody. However, it is also possible that the blood product that resulted in the HTLV-III transmission was administered either during the transplant or shunt removal from a donor who was not contacted.

The appearance of anti-HTLV-III antibody after transplantation demonstrates that the patient was capable of mounting a humoral immune response to new antigens, and supports the hypothesis that he had actually developed AIDS. Antibodies to HTLV-III are uncommon in the general population, and he received plasma only in association with platelet transfusions; thus, it is unlikely that the antibody titer reflects passive transfer of immunoglobulin.[16–18]

In patients who have undergone marrow grafting and in other patients with immunodeficiencies, abnormalities of the helper/suppressor (Leu-3/Leu-2) T cell ratio are difficult to interpret. Evidence from multiparameter flow cytometric analysis of posttransplant lymphocytes shows that in many patients the Leu-2+ cells may not be mature suppressor/cytotoxic T cells by conventional criteria (ie, simultaneously expressing the surface antigens Leu-2 and Leu-4). Leu-2 also appears to be on a subset of natural killer (NK) cells (Leu-2+, Leu-11+, Leu-4−, and cytolytic against K-562). In many transplant patients, these Leu-2+ NK cells predominate during lymphoid regeneration.[13] The presence of large numbers of Leu-2+ NK cells would tend to reduce the "helper/suppressor" ratio as measured by single parameter phenotyping. Therefore, the use of "helper/suppressor" T cell ratios may be misleading in this group of patients. Since his cells were not studied by multiparameter analysis, it is uncertain whether in this case the anti-Leu-2 labelled cells are NK cells or suppressor T cells. However, in this case there was clearly a reduction in the absolute number of Leu-3+ cells. These observations support the suggestion that the quantitation of subsets of T lymphocytes is a more appropriate indicator of HTLV-III infection than subset ratios.[1,5,19]

Although patients who undergo bone marrow transplantation are exposed to blood products from many donors, the risk of transmission of HTLV-III is small. It can be inferred from the recent reduction in the number of 17- to 35-year-old, male blood donors and HBsAg-positive blood donors[20–22] that publicity and FDA[23] guidelines have reduced the numbers of blood donors at high risk for transmitting HTLV-III. The recent general availability of anti-HTLV-III screening of all blood donors is expected to reduce this risk even further. However, due to the variable and long incubation period, some patients transplanted in the last one to five years may still be at risk. When patients without chronic GVHD develop opportunistic infections or lose immune reactivity more than one year after transplantation, consideration should be given to transfusion-associated AIDS.

ACKNOWLEDGMENT

We are indebted to Dr Myron Essex and Mary Fran McLane at the Harvard School of Public Health for performing the anti-HTLV-III assay.

Natural Killer Cell Activity From Hemophiliacs Exhibits Differential Responses to Various Forms of Interferon

By David S. Matheson, Bridget J. Green, Man-Chiu Poon, Marvin J. Fritzler,
David I. Hoar, and Thomas J. Bowen

Patients with hemophilia are at risk for the development of acquired immunodeficiency syndrome (AIDS). Patients with AIDS have recurrent infections and/or malignancy and altered immune response, including decreased T lymphocyte counts, decreased T helper lymphocytes, defective T cell blastogenesis, hypergammaglobulinemia, defective natural killer (NK) activity and impaired response of NK to interferon-β (IFN-β). It is feasible that chronic antigen stimulation with subsequent release of interferon could be related to the impaired NK reactivity to IFN-β of patients with AIDS. Because hemophiliacs are subjected to chronic antigen stimulation secondary to the administration of foreign protein, the reactivity of NK cells from patients with hemophilia to IFN-α, IFN-β and IFN-γ was studied. Eight patients with hemophilia requiring high levels of clotting factor replacement were assessed. Three patients were antibody positive to HTLV-III. All had normal baseline NK cell function. In the first set of experiments, all patients responded normally to in vitro IFN-α by increasing NK activity, but four patients had significant failure and two had mild impairment in NK response to IFN-β. This latter observation was particularly evident at very low concentrations of IFN. In repeated experiments, seven of eight had impaired NK response to IFN-β and IFN-γ but normal response to IFN-α. Only one patient's NK cells responded better to IFN-γ. There was no obvious correlation of these findings to antibody status to HTLV-III. Chronic antigen stimulation and the modulation of interferon receptors are discussed as possible mechanisms that could produce these findings.

ACQUIRED immunodeficiency syndrome (AIDS) was first described in 1981 and is associated with opportunistic infections, malignancy, and abnormal cellular immune reactivity.[1] T cell leukemia virus type III (HTLV-III) is the putative etiologic agent.[2] Cellular immune abnormalities in AIDS include decreased number of helper T cells with decreased ratios of helper to suppressor T cells, decreased blastogenic response of T cells to mitogens and antigens, decreased natural killer (NK) cell level with an impaired response to interferon (IFN)-β and the presence of an acid labile IFN-α in the serum.[3-5] Patients with hemophilia are at risk for the development of AIDS,[6-8] possibly due to the transmissibility of an etiologic factor in blood products. The blood product associated with a higher risk for the development of AIDS in hemophiliacs is the lyophilized factor VIII product,[9,10] perhaps due to the large number of donor plasma units that are pooled to prepare this product. Several groups have reported cellular immune alterations in asymptomatic hemophiliacs.[9-15] Some groups found decreased helper to suppressor T cell ratio secondary to an increase in suppressor cells. Smolen et al demonstrated a decrease in autologous mixed lymphocyte response in hemophiliacs.[14] An increased frequency of activated T cells has been documented.[15]

The purpose of these investigations was to assess the responsiveness of NK cells from hemophiliacs to the various forms of interferon. Like patients with AIDS, it was found that a significant number of patients with hemophilia had a defective NK augmentation to IFN-β. They also had a decreased NK response to IFN-γ but were normally responsive to IFN-α. Unlike AIDS patients, the baseline level of NK was normal.

MATERIALS AND METHODS

Patients. Eight patients with hemophilia were studied. They were men ranging in age from 20 to 59 years. Patients 4 and 6 were factor IX deficient, and the remainder lacked factor VIII. All had procoagulant activity <0.01 U/mL. Replacement of factor during 1983 ranged from 21,000 U to 76,000 U, excluding one patient who required nearly 180,000 U for surgical procedures. Patient 7 had longstanding intermittent thrombocytopenia of unknown etiology. Patients 2, 5, and 7 were known to be antibody positive to HTLV-III. Only patient 3 had no significant titer to cytomegalovirus; all were hepatitis B antigen negative and all were antibody positive to Epstein-Barr virus viral capsid antigen.

Cells. Peripheral blood mononuclear cells (PBMCs) were separated from heparinized blood by centrifugation over Ficoll-Hypaque (Pharmacia, Montreal) from male controls or hemophiliac patients who had given informed consent. After they were washed, the cells were resuspended in RPMI-1640 (GIBCO, Burlington, Canada), in appropriate concentrations. Cell surface markers were performed by cytofluorographic analysis using the following reagents: OKT3, pan T cells; OKT4, helper T cells; OKT8, suppressor T cells; Leu 7, NK cells; and surface Ig, B cells.

Natural killer cell assay. The NK activity was assessed using a standard chromium release assay as published previously.[16] In brief, PBMCs were mixed with 10^4 K562 cells (Institute for Medical Research, Camden, NJ) which had been labeled with ^{51}Cr (Amersham, Montreal) to yield ratios of 30:1, 10:1, 3:1, and 1:1 effector to target cells; the cells were incubated for 16 hours. Percentage of lysis and lytic units per 10^7 cells were calculated according to standard techniques.[17] IFN-α and IFN-β were supplied in a partially purified form[18,19] by Dr Y. H. Tan, University of Calgary, Alberta, Canada. IFN-γ was purchased from Mulloy (Springfield, Va). Effects of IFN on the NK cell assay were assessed by preincubating 2×10^6 PBMC with varying amounts of IFN for two hours prior to aliquoting the cells into the microtiter plate for assessment of NK activity.

Delayed hypersensitivity skin testing. The CMI-Multitest kit (Rhone-Poulenc, Montreal) was used.[20] The quantitative and qualitative responses were recorded at 48 hours as recommended by the supplier.

RESULTS

All patients had white blood cell counts above 3.0 × 10^9/L, and only patient 7 had lymphopenia of $<1 \times 10^9$ lymphocytes/L. Patient 7 also had a platelet count of 76 × 10^9/L; the platelet counts of the other patients were normal. Hypergammaglobulinemia was present in patients 2, 5, 6, and 8 in the IgG fraction. Patient 5 had an elevated IgA and patient 2 had an increase in his IgM level. The hypergammaglobulinemia was polyclonal in all cases as judged by protein electrophoresis. All patients had positive responses to at least one of the antigens tested by delayed hypersensitivity skin testing, using the CMI Multitest with a minimum recorded response of 3 mm of induration. Hence, none of the patients was completely anergic (data not shown).

Standard cell surface markers were assessed using monoclonal antibodies and a Becton Dickinson cytofluorograph (Table 1). All except patients 2 and 7 had an adequate percentage of T cells, and all except patients 5 and 7 had an adequate percentage of OKT4+ cells. Patient 5 had a decreased percentage of suppressor T cells. Patient 7 had decreased absolute helper and suppressor cell numbers. In patient 7, the helper (OKT4) to suppressor (OKT8) ratio was 0.6, for all others, it was >1.0. The percentage of Ig-positive B cells was normal and ranged from 5% to 11%. The percentage of Leu-7–positive cells ranged from 8% to 22% and was within normal limits. Hence, those patients with abnormalities in lymphocyte markers were those who had antibody to HTLV-III (patients 2, 5, and 7 from Table 1).

The baseline level of NK cell activity was adequate (Fig 1). Most patients did not respond well to IFN-β, but did respond to IFN-α. IFN-β at 100 U/2 × 10^6 PBMCs in 0.6 mL of medium failed to induce (or induced to a lesser extent) increments in the percentage of lysis when compared with IFN-α. The NK activity of PBMCs from hemophilia patients averaged 60.6% (± 11.2%) when incubated with IFN-α and 50.4% (± 7.3%) when treated with IFN-β. The baseline NK average was 48.0% (± 8.8). Using a paired *t* test, there was a significant difference between the IFN-α–induced and IFN-β–induced responses ($P < .001$). The NK response of PBMCs from controls run simultaneously with the hemophiliac PBMCs did not reveal any significant difference in response to IFN-α or IFN-β.

Table 1. Lymphocyte Markers and HTLV-III Antibody Status

Patient	OKT3	OKT4	OKT8	H/S Ratio	HTLV-III Antibody
1	74	29(574)	28(554)	1.1	–
2	41	21(222)	11(116)	1.9	+
3	56	25(380)	11(167)	2.2	–
4	53	27(518)	26(499)	1.0	–
5	68	11(335)	7(213)	1.6	+
6	54	28(541)	24(464)	1.2	–
7	28	12(100)	19(158)	0.6	+
8	56	34(571)	15(252)	2.3	–
Normal	50–70	20–46	10–35	>1.0	–

Marker data are expressed as percentage of peripheral blood mononuclear cells. Numbers in parentheses are WBC times percentage of lymphocytes times percentage of OKT reagent expressed as cells × 10^6/L.

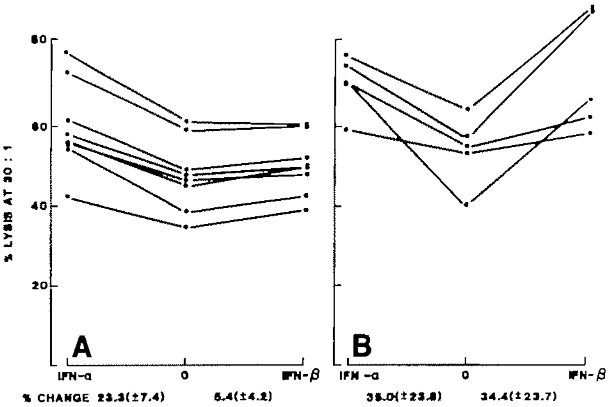

Fig 1. NK activity of the hemophilia patients (A) or controls (B) is shown at baseline prior to (center) and subsequent to exposure to interferon (IFN)-α (left) or IFN-β (right of each panel). IFN concentration was 100 U/2 × 10^6 peripheral blood mononuclear cells (PBMC) in 0.6 mL and natural killer (NK) activity is recorded at a 30:1 effector to target ratio. The average percentage of increase induced by each type of IFN [(NK with IFN–NK without IFN)/NK without IFN] times 100 is given below the figure.

To assess this phenomenon further, the response of the NK cells to low concentrations of IFN-α and IFN-β was assessed in four separate experiments (Fig 2). The control PBMCs demonstrated the same dose–response curves to IFN-α as to IFN-β. However, the PBMCs of the hemophilia patients 1, 5, 6, and 8 were markedly less responsive to IFN-β than to IFN-α. Patients 2 and 3 demonstrated the same pattern, but to a lesser degree; only patient 4 responded better to IFN-β. Patient 8 was assessed on two separate occasions; the results were reproducible in that each time the PBMCs responded to IFN-α but essentially did not respond at all to IFN-β. Hence, the NK response to IFN-β was significantly depressed in four of eight patients and mildly depressed in 2 others.

All patients were reassessed again in terms of their responsiveness to all three types of IFN, α, β and γ. From Fig 3, it can be seen that control PBMCs tend to respond similarly to IFN-α, IFN-β and IFN-γ. However, patients with hemophilia responded normally to IFN-α but poorly to IFN-β and IFN-γ (patients 2, 3, 4, 5, 6, and 8). Patient 1 responded better to IFN-γ and demonstrated no real difference in response to IFN-α and IFN-β. Patient 7 did not show any significant defect in response to the three forms of IFN.

Therefore, most patients with hemophilia demonstrated a defective NK response to IFN-β and IFN-γ but normal response to IFN-α. Although some exceptions in reproducibility exist (eg, patients 1 and 4 in Figs 2 and 3), most patients have a consistently impaired NK response to IFN-β (Figs 1, 2, and 3).

DISCUSSION

These data indicate that most patients had essentially normal routine hematology and marker data. Minor aberra-

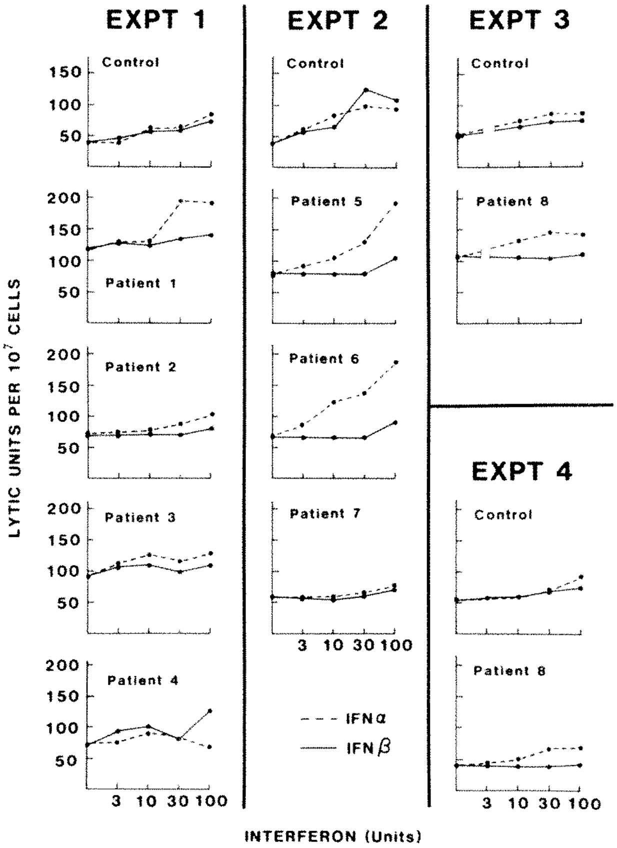

Fig 2. Four experiments comparing the natural killer (NK) response of PBMC from patients or controls to IFN-*α* (- - - -) or to IFN-*β* (——) are shown. IFN concentrations are expressed as U/2 × 10^6 peripheral blood mononuclear cells in 0.6 mL. NK activity is expressed as lytic units per 10^7 effector cells.

tions were present, especially in those who were antibody positive to HTLV-III. All patients were asymptomatic at the time of testing. The raised IgG or IgA in four of eight patients were polyclonal in nature. Taken together, these results may be more consistent with chronic antigen stimulation than with AIDS. However, since patients with AIDS have impaired NK response to IFN-*β*,[4] similar studies were performed with PBMCs from hemophiliacs.

The PBMCs from most patients with hemophilia failed to increase in NK level in response to IFN-*β* and IFN-*γ*. IFN-*β* is a glycoprotein secreted from fibroblasts during viral infections.[21] IFN-*α* is derived from white cells secondary to viral infection. IFN-*γ* is derived from blast-transformed lymphocytes. IFN-*β* and IFN-*γ* are glycoproteins in that they bind to Concanavalin-A (Con A) whereas IFN-*α* does not.[22,23] The receptor studies for IFN-*α*, -*β* and -*γ* (although not performed on NK cells) indicate that IFN-*β* can inhibit binding of IFN-*α* and IFN-*γ*, but that IFN-*α* and IFN-*γ* do not compete for the same binding sites.[24-27] This has been interpreted to mean that the receptor for IFN-*β* and IFN-*γ* may be carbohydrate dependent, but that the receptor for IFN-*α* and IFN-*β* is protein defined.[25] It is known that the presence of IFN in culture systems will decrease the number of IFN receptors.[28] The chronic exposure to IFN-*β* or IFN-*γ* could decrease this receptor density and impair responsiveness to IFN-*β*. Hence, it is feasible that there has been down modulation in the IFN-*β* and IFN-*γ* receptor. This is consistent with the argument presented for the diffuse hypergammaglobulinemia; that is, hemophiliacs are exposed to chronic antigen stimulation. The activated lymphocytes could then sustain increased IFN-*γ* levels and down regulate IFN-*γ* and IFN-*β* receptors. It has been shown that some patients with AIDS have an abnormal acid labile IFN-*α* present in their serum.[5] A similar acid-labile IFN-*α* has been demonstrated in 3 hemophiliacs prior to the onset of AIDS and was seen transiently in 3 of 46 asymptomatic hemophiliacs.[29] It is not

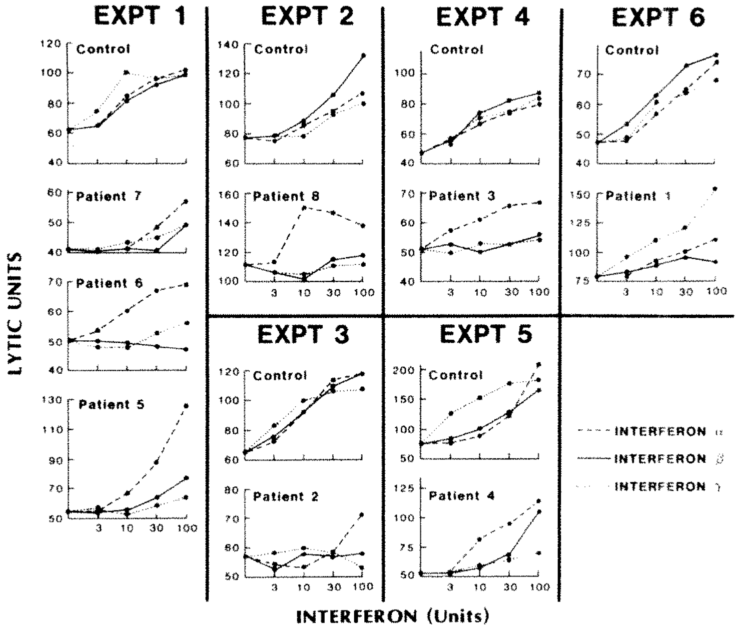

Fig 3. Six experiments comparing the natural killer (NK) response of peripheral blood mononuclear cells of patients and controls to IFN-*α* (- - - -), IFN-*β* (——), IFN-*γ* (· · · · ·) are shown. NK activity is expressed as in Fig 2.

known if this abnormal IFN modulates cellular reactivity through the IFN-α receptor.

Therefore, there is evidence for an impaired NK augmentation secondary to IFN-β and IFN-γ which was common in patients with hemophilia and which did not correlate with the presence of antibody to HTLV-III. These data are consistent with the suggestion that the receptors for IFN-β and IFN-γ are correlated, if not identical, and the receptor for IFN-α is different. Down modulation of IFN receptors may be secondary to chronic antigen stimulation, presumably as a result of the continuous requirement for foreign protein related to coagulant therapy.

ACKNOWLEDGMENT

We thank Grace Lavernge and Kathy Bennett for their nursing assistance, Dr. T. Zipf and L. Bryant for the cytofluorographic analysis, and Dr A. Landay of Rush–Presbyterian St Luke's Medical Centre, Chicago, for the HTLV-III antibody status.

Expression of a Cloned Lepore Globin Gene

By Carl Dobkin, Jennifer Clyne, Aida Metzenberg, and Arthur Bank

Lepore globin is synthesized in markedly diminished amounts (~10% to 15% of normal β-globin) in human erythroid cells. To study the molecular mechanisms responsible for the diminished biosynthesis of Lepore globin, the Lepore–Boston gene was cloned from a charon phage DNA library and expressed in HeLa cells. Northern blotting and S1 nuclease analyses indicated that the Lepore gene produced less globin mRNA than a β-gene and more than a δ-gene. The results indicate that expression of the Lepore–Boston gene in HeLa cells is reduced to an extent comparable to that seen in erythroid precursors in vivo. This indicates that the decrease in Lepore globin gene transcription is due to the δ-nucleotide sequences either in the 5′ flanking region or within this gene.

© *1986 by Grune & Stratton, Inc.*

LEPORE GLOBINS are fusion products of δ- and β-polypeptide components.[1,2] Lepore–Boston consists of δ-globin sequence from its N terminal end to amino acid 87, and β-globin sequence from amino acid 116 to its C terminal end.[3] The crossover from δ-sequence to β-sequence in this Lepore gene has been studied by restriction analysis and has been shown to be near the 5′ end of the large intervening sequence (IVS 2), a region of strong homology between the δ- and β-genes.[4] Lepore globin is present in reduced amounts relative to normal β-globin levels in both heterozygotes and homozygotes. Lepore globin mRNA is present in reduced quantities as well, indicating that the decreased production of Lepore globin is due either to decreased transcription of the Lepore globin gene or to abnormal processing or instability of the Lepore globin mRNA.[5] To investigate this RNA reduction, we transferred a cloned Lepore globin gene into tissue culture cells and analyzed its expression. The results indicate that Lepore globin mRNA accumulates in HeLa cells transfected with this gene at a lesser rate than with a normal β-globin gene and at a greater rate than with the normal δ-globin gene. This is consistent with the relative expression of each of these genes in erythroid cells in vivo. The lack of aberrant splice products in the HeLa cell transcripts suggests that the decreased expression of the Lepore globin gene is due to decreased transcription or mRNA stability.

MATERIALS AND METHODS

A Lepore–Boston gene was cloned from a library of DNA fragments inserted into charon 27 and isolated by one of us (A.M.) from a typical patient (L.P.)[6] homozygous for hemoglobin Lepore–Boston.[4,5] The *Pst*I fragment containing the Lepore globin gene was subcloned into a plasmid, pBSV,[7] at the *Bam*HI site (Fig 1). To do this, we synthesized (on an Applied Biosystems Synthesizer) an eight-base oligomer, GATCTGCA, which is complementary to the *Pst*I and *Bam*HI overhanging ends. The ligation of this oligomer to the Lepore globin *Pst*I fragment[8] resulted in a fragment that could be inserted into the *Bam*HI site of pBSV (Fig 1). This plasmid contained approximately 0.5 kilobases (kb) of sequence 5′ to the structural Lepore globin gene and ~0.5 kb of 3′ to this gene. In these studies, δ-pBSV was also constructed from a *Pst*I fragment of an isolated δ-gene. The β-pBSV was also constructed, using a *Bgl*II fragment containing a normal β-globin gene that has ~1.5 kb of 5′ flanking sequence and 1.8 kb of 3′ flanking sequence.

HeLa cells were transfected with these plasmids using DEAE-Dextran.[9,10] RNA was isolated after 48 hours by cesium chloride sedimentation.[11] RNA was analyzed by Northern blotting,[12] by S1 nuclease protection,[10,13] and by RNAase protection when an RNA probe was used.[14] Three different probes were used in the analyses: a β-globin gene segment extending from the *Bal*I site 5′ to the gene to the *Eco*RI site in exon 3, in bacteriophage M13 mp 7, was used as template for synthesis of uniformly labeled probe.[13] A Lepore globin gene fragment extending from the 5′ *Pst*I site to the *Eco*RI site in coding region 3 was used in the same way. An RNA probe was prepared by inserting a *Bal*I–*Eco*RI fragment of the β-globin gene "downstream" from the SP6 promoter in the vector pSP62; uniformly labeled RNA was transcribed from this insert by SP6 RNA polymerase[14] using the instructions of the supplier (Promega Biotec or New England Nuclear, Boston). A 2.3-kb *Kpn*I–*Bam*HI SV 40 fragment was "nick translated" to probe Northern blots for T antigen transcripts.

Northern blots were prepared after agarose gel electrophoresis in the presence of formaldehyde[12] and were hybridized with β-globin probe. Uniformly labeled RNA probe at 0.3 Ci/mg was able to detect Lepore transcripts. S1 nuclease mapping was carried out using the Lepore and β-DNA probes.[10,13] A ^{32}P-labeled RNA probe was used in the analysis of globin transcripts in ribonuclease mapping experiments by hybridization of the cellular RNA with the probe and treatment of the hybrids with ribonucleases A and T1.[14]

RESULTS

RNAs transcribed in HeLa cells from the Lepore, β-, and δ-pBSV constructs were compared. A "nick-translated" β-globin probe was used in initial Northern blotting experiments, which showed a strong signal from the β-pBSV transcripts, but no signal in RNA from HeLa cells transformed with either the Lepore plasmids or the δ-plasmids (data not shown). This implied that β-globin mRNA accumulates in much higher quantities than δ- and Lepore RNAs. To improve the detection of Lepore RNAs and δ-RNAs, a uniformly labeled RNA probe representing the *Bal*I–*Eco*RI globin region was synthesized with bacteriophage SP6 RNA polymerase.[14] In this experiment, the β-globin RNA signal could easily be seen, and a weaker but detectable signal was also seen with the Lepore globin gene in the 10S RNA region (Fig 2A). There was no visible

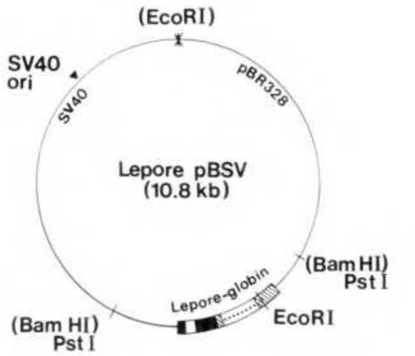

Fig 1. Lepore pBSV expression plasmid. The *Pst*I fragment of the cloned Lepore gene was ligated to a synthetic oligomer, GATCTGCA, in order to create a *Bam*HI end, and inserted into the *Bam*HI site of pBSV. The *Eco*RI site of pBSV had been eliminated. The *Pst*I fragment contains approximately 0.5 kb 5′ and 0.5 kb 3′ to the gene, which is shown cap site to poly A site, left to right. Open rectangles indicate IVS 1 (δ-sequence). Open rectangle with dots indicates IVS 2 (β-sequence). Solid rectangles indicate exon I and part of exon II, which are δ-sequence. Hatched rectangles indicate the remainder of exon II and exon III, which are β-sequence.

δ-globin signal, however. To provide an internal control for plasmid transfection and RNA recovery, RNA from cells transfected with β- and Lepore globin gene containing plasmids were assayed for the presence of transcripts from the plasmid T antigen gene. RNA from cells transfected with either Lepore globin plasmids or β-globin plasmids contains similar amounts of SV 40 T antigen RNA (Fig 2B). Thus, the decrease in Lepore globin mRNA as compared with β-globin mRNA in these same RNA samples is not due to differences in transfection or RNA isolation, but to differences in expression of the β-globin genes and the Lepore globin genes. These results indicate that the Lepore globin gene is expressed in HeLa cells at a level less than that of the β-globin gene and greater than that of the δ-globin gene, which is consistent with the expression of these genes in erythroid cells in vivo.

To further investigate the transcription and processing of RNA from these cloned genes, we analyzed them by S1 nuclease mapping. Using a Lepore DNA probe, a signal was seen with RNAs from HeLa cells transfected with β and Lepore genes but not consistently from those with the δ gene. The Lepore segments protected by Lepore RNA are, as expected, only the 145, 225 and 49 classes representing exons I, II, and part of III (Fig 3). The β-globin gene transcripts protected the same 145, 225, and 49 classes, as well as the 160 and 65 sizes, representing further cleavage of the 225 exon II fragment. The signal is much weaker with RNA from cells transfected with the δ-globin gene. No unexpected fragments were protected by the β-transcripts, the Lepore transcripts, or the δ-transcripts, indicating the absence of aberrant splicing. When a β-globin DNA probe was used, the probe segments protected by β-globin RNAs and Lepore globin RNAs were consistent with the predicted homology to the probe; β-globin RNA protects segments of 145, 225, and 49 bases, representing exons I, II, and part of III (Fig 4A). Lepore RNA signal was weaker than β-globin RNA signal even though twice as much Lepore RNA was used.

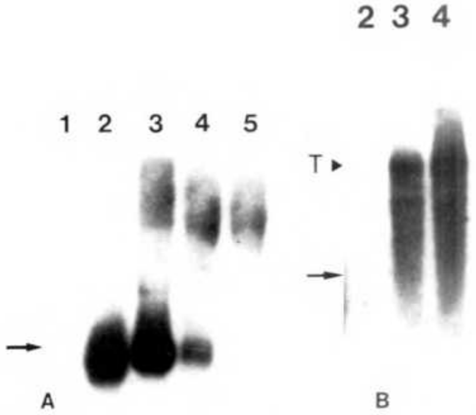

Fig 2. (A) Northern blot analysis of Lepore gene transcripts. Total RNA from HeLa cells transfected with β-, Lepore, or δ-globin gene plasmids was fractionated on 1% agarose gels in the presence of formaldehyde, transferred to nitrocellulose membrane, and hybridized with uniformly labeled RNA representing part of the β-globin gene. Lane 1: 25 μg HeLa RNA (no plasmid). Lane 2: 0.020 μg RNA from human reticulocytes containing approximately 1% β-globin mRNA. Lane 3: 25 μg RNA from HeLa cells transfected with β-globin plasmid. Lane 4: 25 μg RNA from HeLa cells transfected with Lepore plasmid. Lane 5: 25 μg RNA from HeLa cells transfected with δ-globin plasmid. Arrow at left points to the region that contains normal β-globin transcript (10S). (B) Northern blot analysis of "control" T antigen transcripts. Samples of the RNA analyzed in (A) were fractionated and transferred as in (A) and hybridized with nick-translated DNA containing the SV 40 T antigen region. Lane 2: 0.02 μg reticulocyte RNA. Lane 3: 25 μg RNA from HeLa cells transfected with β-globin plasmid. Lane 4: 30 μg RNA from HeLa cells transfected with Lepore plasmid. All the transfected plasmids contain the T antigen gene, and its transcription should be independent of the globin gene insert. The T antigen signal (T in margin) indicates that the transfection of the β-globin and Lepore plasmids was equivalent, as was the recovery of the transcribed RNA. This blot was rehybridized with a β-globin probe (as in [A]) (data not shown); the β-globin lane gave a strong 10S signal (at arrow), while only a trace of hybridization was detected in the Lepore lane.

When an RNA probe identical to the β-globin DNA probe was hybridized to β-, δ- and Lepore RNAs, and the hybrids are digested with RNAase A and T1, essentially the same pattern of signals is seen as with the DNA probe (Fig 4B). Again, the signal was greatest with β-RNA and substantially reduced with Lepore RNA. The signal with Lepore RNA was again greater than with the δ-RNA.

DISCUSSION

A cloned Lepore–Boston globin gene has been expressed in HeLa cells, and its expression compared to cloned normal δ- and β-human globin genes in this system. The results indicate that the Lepore globin gene is intermediate in its expression between that of normal β- and normal δ-genes, similar to the situation that occurs in vivo in human bone marrow. This suggests that the expression of these transfected genes is regulated by sequences contained within the fragments of DNA transfected. The Lepore gene differs from the β-gene by having δ-sequences in the 5′ flanking region as well as in exon I, the small intervening sequence (IVS 1), and exon II. The decreased expression of the Lepore

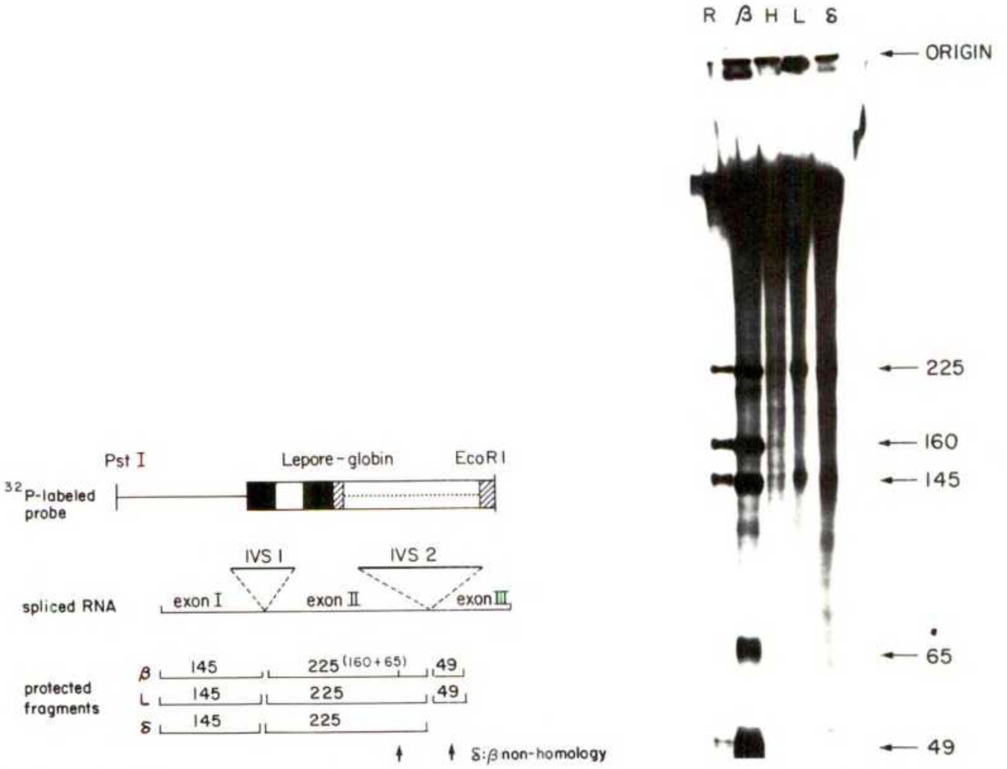

Fig 3. S1 mapping of HeLa cell transcripts with Lepore probe. RNA from HeLa cells transfected with β-, Lepore, or δ-globin gene plasmids was hybridized to uniformly lableled DNA, the hybrids were digested with S1 nuclease, the probe fragments were separated on 5% polyacrylamide (19:1, acrylamide:bis acrylamide; 7 mol/L urea) and visualized by autoradiography. The probe was synthesized on a single-stranded template representing the *Pst*I-*Eco*RI segment of the Lepore gene and isolated after *Pst*I and *Eco*RI digestion. In the scheme at bottom, the probe is represented as nontranscribed region (line); exon I and part of exon II, which are δ-sequence (solid rectangles); IVS 1, which is δ-sequence (open rectangle); part of exon II and exon III, which are β-sequence (hatched rectangle); and IVS 2, which is β-sequence (open rectangle with dots). The derivation of probe fragments protected by the different RNAs is also diagramed at bottom. Fragments protected by β-RNA are 145 bases (exon I), 225 bases (exon II), and 49 bases (part of exon III); nonhomology between probe and transcript (arrows at bottom) leads to some S1 cleavage of exon II fragment into 160- and 65-base fragments. (See lanes R and β.) Fragments protected by Lepore RNA are 145 bases (exon I), 225 bases (exon II), and 49 bases (part of exon III). (See lane L.) Fragments protected by δ-RNA are 145 bases (exon I) and 225 bases (exon II); nonhomology in exon III between probe and δ-transcript prevents protection in this region. (See lane δ.) Lane R: protection by 0.020 μg RNA from human reticulocytes (65-base signal is very light). Lane β: protection by 50 μg RNA from HeLa cells transfected with β-globin plasmid. Lane H: protection by 50 μg RNA from HeLa cells (no plasmid). Lane L: protection by 100 μg RNA from HeLa cells transfected with Lepore plasmid (49-base signal is very light). Lane δ: protection by 100 μg RNA from HeLa cells transfected with δ-globin plasmid.

gene as compared with the normal β-globin gene is probably due to these δ-sequences.

A gene constructed in vitro that resembles the Lepore gene also gives markedly decreased expression when transfected into a line of monkey kidney cells.[15] (In these experiments, the *Bam*HI 1.8-kb fragment of the δ-gene was ligated to a 3′ β-fragment at the common *Bam* site within these genes.) Recent experiments in our laboratory[16] indicate that the expression of a β-globin gene in HeLa cells is not decreased by substitution of a δ-IVS 1 for a β-IVS 1. Because exons I and II of these genes are >90% homologous, these results suggest that the δ 5′ flanking sequences of the Lepore gene are responsible for its decreased expression compared with the normal β-globin gene. Other experiments in our laboratory indicate that substitution of δ-IVS 2 for β-IVS 2 leads to markedly reduced expression. Thus, δ-IVS 2 either decreases the expression of a β-globin gene or β-IVS 2 is required for the high-level expression of this gene. The presence of β-IVS 2 in the Lepore globin gene may explain why it is expressed at a higher level than the δ-globin gene. Thus, elements within as well as flanking the δ- and β-globin genes seem to control their activity—the 5′ flanking region and IVS 2. The Lepore gene with a 5′ δ-flanking region, but a normal β-IVS 2, has a higher rate of expression than the normal δ-gene. These experiments do not directly demonstrate the precise step in RNA synthesis responsible for decreased Lepore mRNA accumulation. In addition, further experiments are required to determine whether the 5′ flanking regions and IVS of the δ-, β-, and Lepore genes have these effects when the cloned genes are expressed in erythroid cells.

ACKNOWLEDGMENT

We thank Oona Collins for preparing this manuscript.

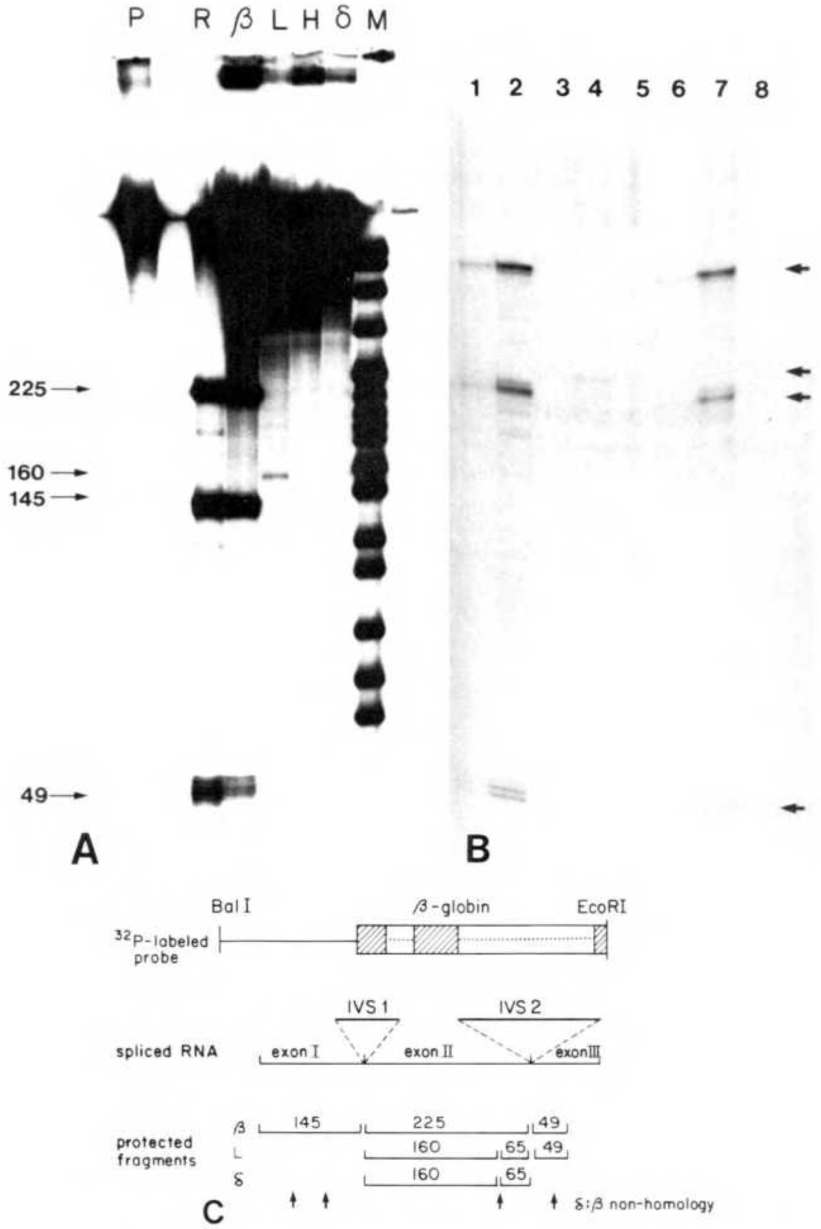

Fig 4. (A) S1 mapping of HeLa cell transcripts with β-globin DNA probe. RNA from HeLa cells transfected with β-, Lepore, and δ-globin gene plasmids was hybridized to uniformly labeled DNA, the hybrids were digested with S1 nuclease, the probe fragments were separated on 5% polyacrylamide (19:1, acrylamide:bis-acrylamide; 7 mol/L urea) and visualized by autoradiography. The probe was synthesized on a single-stranded template representing the *Bal*I–*Eco*RI segment of β-globin DNA and isolated after restriction enzyme digestion. In (C) the probe is represented as nontranscribed region (line), exons I, II, and part of III (hatched rectangles), and IVS 1 and 2 (open rectangles with dots). The derivation of probe fragments protected by the different RNAs is also diagramed at bottom. Fragments protected by β-RNA are 145 bases (exon I), 225 bases (exon II), and 49 bases (part of exon III). (See R and β.) Fragments protected by Lepore RNA are 160, 65 (representing parts of the 225-base exon II segment which is cleaved by S1 due to nonhomology between probe and transcript), and 49 bases (part of exon III). (See L.) Fragments protected by δ-transcripts are 160 and 65 bases (representing exon II), and the same fragments are seen with Lepore transcripts. (See lane δ.) Lane P: undigested probe. Plasma-Mediated Alterations of Erythrocyte Deformability by Perfluorochemical Blood Substitutes

By Gretchen M. Holloway, E.A. O'Rear, and B.M. Fung

The effect of perfluorochemical blood substitutes (eg, Oxypherol or Fluosol-DA) on red cell deformability was investigated because these emulsions are in direct contact with red cells when they are used as temporary circulatory aids. Erythrocyte deformability was assessed by a constant volumetric flow rate filtration method. The results of in vitro incubation experiments indicate that perfluorotributylamine causes the deformability of human red cells to decrease significantly in the presence of plasma. However, there is no obvious loss in the deformability when washed cells are used. Neither mean cell volume nor white cells appear to be responsible for the observed effects of perfluorotributylamine. Perfluorodecalin and perfluorotripropylamine, two perfluorochemical compounds that are widely applied clinically, do not induce significant changes in red cell deformability with or without plasma. These results indicate the need for in vitro testing in the development of perfluorochemicals as blood substitutes.

© 1986 by Grune & Stratton, Inc.

PERFLUOROCHEMICAL (PFC) blood substitutes are being actively developed and tested in many countries. They have the potential to provide a temporary circulatory aid, which could alleviate many current problems with transfusions, namely, availability and storage of blood, matching of blood types, and disease transmission. In addition, PFC suspensions show promise in several medical procedures, including the perfusion of donor organs,[1] the treatment of ischemia,[2-4] the improvement of coronary angioplasty,[5] and the enhancement of radiation therapy of tumors.[6]

Development of these red cell substitutes has not been without complications. For example, vapor emboli and prolonged retention times were observed in animal studies of early candidate PFCs. More recently, clinical trials in the United States have indicated increased pulmonary artery pressures, bradycardia, and chest pain[7] and complement activation[8] in some patients after the infusion of Fluosol-DA. With intimate contact between the PFCs and blood components, we anticipated that problems could arise if erythrocyte deformability were affected.

The determining factor of the life span for a typical red cell appears to be the deformability of that cell.[9] As the cell stiffens with age, it becomes more susceptible to splenic sequestration and removal from the circulation. Abnormal red cell flow properties, as measured by a variety of techniques, have been implicated as one mechanism of cell loss in a number of diseases and clinical conditions.[10,11] As a factor in certain types of anemia, reduced deformability translates to an accelerated rate of removal of cells by the microcirculation.

As a consequence of abbreviated red cell life spans, altered flow properties in the presence of a PFC could cause decreased tissue perfusion. Hence, the effect of PFC emulsions on erythrocyte deformability is an appropriate concern in their development as blood substitutes. The potential significance of this problem is augmented by the short half-lives for the current PFC emulsions,[12,13] so that the responsibility for oxygen transport requirements must be rapidly reassumed by the patient's own erythrocytes.

To date, no one has investigated erythrocyte deformability after exposure to PFC suspensions, even though the results of related experiments present reason for concern. In mongrel dogs, for instance, increased postmortem liver and spleen weights and larger-than-normal red blood cell volumes have been associated with the use of PFC suspensions.[14] In baboons infused with a PFC emulsion, hematocrit continued to decline beyond the hemodilution level after infusion.[15] Moreover, direct observation of red blood cells in vivo within the microvasculature of rabbit omentum has shown crenated red cells and erythrocytic debris on infusion of emulsions of perfluorotributylamine.[16,17] Using a filtration method, we have studied the effect of several PFCs on the deformability of erythrocytes. The PFC systems studied were Oxypherol, Fluosol-DA, and other emulsions prepared in this laboratory. Compositions of these systems are described later in detail.

MATERIALS AND METHODS

Erythrocytes were obtained from fresh human blood donated by healthy, nonsmoking male volunteers from whom prior informed consent had been obtained. Whole blood was used directly for some incubations, but in each case, red cells were resuspended in Ringer's/human albumin before the deformability test. Erythrocyte samples were washed twice each with normal saline and then Ringer's solution. Washing involved centrifugation, removal of supernatant, and resuspension of the cells in order to remove plasma and most of the white blood cells. Finally, the washed cells were resuspended in a solution appropriate for the ensuing procedure.

Erythrocyte deformability was measured using a constant volumetric flow rate filtration technique, in which pressure is used as an indication of the flow resistance through the 3-μm pores of a Nuclepore filter. The pressure *v* filtration time curve becomes linear with a slight positive slope after a short transient period; an initial pressure drop (P_0) is obtained by extrapolation of the linear region back to zero time when plugging by contaminant white cells or thrombi does not occur. Tests in this study were at a volumetric flow rate of 2 mL/min and hematocrit of 3% to 4% in Ringer's/human albumin. Details of the filtration method have been described previously.[18,19] Cell counts for each sample were adjusted with a Boehringer-Mannheim HC-333 cell counter (Houston); the hemato-

crit was determined in duplicate by the microhematocrit method. Cell morphology was checked by light microscopy of wet mounts.

In order to investigate the mode by which the PFCs may affect the deformability of erythrocytes, the blood samples were treated in several ways:

1. The erythrocytes were harvested immediately after the blood was drawn, resuspended in a 0.05 g/L Ringer's albumin (human) solution, and then incubated with Oxypherol.
2. Whole blood was incubated with Oxypherol, or another PFC emulsion to be tested, before the erythrocytes were separated.
3. White cells, for the most part, were removed from the whole blood; the recombined plasma and erythrocyte suspension was subsequently incubated with Oxypherol.
4. The plasma was first incubated at 56 °C for one hour to denature the proteins; then it was centrifuged to remove the flocculated proteins; finally, the cells were resuspended in the treated plasma and mixed with Oxypherol before incubation.

Samples were washed and the PFCs removed before the filtration tests. Oxypherol and Fluosol-DA emulsions and annex solutions were obtained from Alpha Therapeutics Corporation and prepared according to instructions. Except where noted, incubations were at 37 °C for four hours; the total time for workup, incubation, and measurements was less than eight hours in all experiments. PFC emulsions were added to 10 vol%, roughly equivalent to the transfusion of 1 unit. In each case, a control was run with cells prepared in a similar manner but without the PFC emulsion.

RESULTS AND DISCUSSION

When Oxypherol was added to washed erythrocytes, with incubation, it did not affect the deformability of the erythrocytes (Table 1, part A). However, when Oxypherol was first incubated with whole blood (Table 1, part B) or plasma (Table 1, part C), it caused the erythrocytic deformability to decrease significantly (Gosset's *t* test). To confirm that the flow properties had been altered, viscosities of red cell suspensions (70% hematocrit) obtained from paired whole blood samples incubated four hours with and without Oxypherol were measured in a capillary tube viscometer (1.15-mm ID). At wall stress $\tau_w = 2.99$ dyn/cm^2, suspension viscosity increased after incubation with Oxypherol (controls, 13.5 ± 2.6 cp (5); Oxypherol, 16.2 ± 4.4 cp (5); $P < .15$). A high hematocrit was used in these tests because, according to Dintenfass,[20] red cell "rigidity" becomes a significant factor for viscosity only at higher cell concentrations. The mean cell volume (MCV) was calculated, and unlike previous results for canine cells, no changes due to experimental procedures were observed (Table 2), although the MCV varied slightly among individuals. Results for MCV compared favorably with reference values for normal cells.[21,22] Resuspended in Ringer's/albumin, red cells for all samples exhibited normal morphology. The deformability tests indicate that one or more of the components in the plasma causes the Oxypherol to interact with the erythrocytes. When the plasma was first incubated at 56 °C for one hour (and the denatured proteins were removed before being incubated with the red cells and Oxypherol), the effect of the PFC emulsion on the erythrocyte deformability was reduced (Table 1, part D). However, there was also an apparent increase in the erythrocytic deformability (ie, the pressure drop decreased) of the denatured-plasma control compared with the whole blood control. As a result, a difference between the control and the sample treated with Oxypherol was still observed in this case; but unlike samples incubated with undenatured plasma, this difference was not statistically significant. Therefore, we speculate that the decrease in the red cell deformability may be due to plasma protein-mediated transfer of the PFC component in Oxypherol to the membrane of the erythrocyte. The validity of this hypothesis and the component responsible for the transport of the PFC remains to be tested. Alternatively, the particular mechanisms of reduced deformability might be enhanced platelet activation[23] or protein adsorption. The former of these two is particularly suspect, since a recent report indicates that platelet activation can affect red cell deformability.[24] Additional studies are planned to investigate these mechanisms. Because results for recombined plasma with Oxypherol were similar to those for whole blood with Oxypherol, it appears that white blood cells are not responsible for the observed changes (Table 1, parts B and C).

Table 1. Results of Erythrocyte Deformability Measurements

Samples	Composition	Initial Pressure Drop (mm Hg) ± SD	Statistically Significant Difference ($P < .01$)
A. Prewashed cells	Control	21.2 ± 1.5 (5)	—
	Oxypherol	21.8 ± 2.3 (5)	No
B. Whole blood	Control	19.2 ± 2.7 (12)	—
	Oxypherol	26.0 ± 3.8 (12)	Yes
	Oxypherol ± PC	27.0 ± 2.9 (4)	Yes
	PFTBA ± PFD	28.4 ± 1.9 (4)	Yes
	Fluosol-DA	21.9 ± 0.2 (3)	No
	Pluronic F-68	18.5 ± 1.2 (4)	No
C. Plasma	Control	19.3 ± 3.4 (6)	—
	Oxypherol	24.9 ± 1.3 (6)	Yes
D. Denatured plasma	Control	14.8 ± 5.1 (5)	—
	Oxypherol	18.6 ± 8.8 (5)	No

A larger pressure drop of a sample compared with the control indicates a loss in deformability. The last column shows whether or not the difference between the sample and the corresponding control is statistically significant within a 99% confidence limit. PC, phosphatidylcholine; PFTBA, perfluorotributylamine; PFD, perfluorodecalin.

Table 2. Mean Cell Volume After Incubation for Four Hours at 37 °C

Samples	Composition	MCV (μm^3) ± SD	Statistically Significant Difference ($P < .01$)
Prewashed cells	Control	81.7 ± 11.4 (3)	—
	Oxypherol	88.8 ± 6.2 (3)	No
Whole blood	Control	88.9 ± 4.8 (11)	—
	Oxypherol	92.2 ± 6.4 (10)	No
	Oxypherol + PC	89.9 ± 3.0 (4)	No
	PFTBA + PFD	89.4 ± 1.2 (4)	No
	Fluosol-DA	90.1 ± 4.2 (3)	No
	Pluronic F-68	88.4 ± 2.8 (4)	No
Plasma	Control	84.3 ± 5.4 (6)	—
	Oxypherol	87.1 ± 8.7 (6)	No
Denatured plasma	Control	85.6 ± 3.8 (5)	—
	Oxypherol	90.0 ± 3.6 (5)	No

Previous workers have related toxicity of some PFC emulsions to particle size. Electron microscopy results show that, when prepared by established methods, the average particle diameter of perfluorotributylamine (PFTBA)-Pluronic F-68 emulsions corresponds to a safe value for infusion.[25] Similarly, the mean particle size for perfluorodecalin–perfluorotripropylamine (PFD–PFTPA) and Pluronic F-68 emulsions is reported to be 0.1 μm.[26,27] According to literature supplied by Alpha Therapeutics, Oxypherol and Fluosol-DA emulsions have an average particle size of 0.1 to 0.2 μm. Using a centrifugation method,[28] we obtained mean particle sizes of less than 0.12 μm for Fluosol-DA and of 0.25 μm for Oxypherol.

Because we found that the Oxypherol decreases the deformability of erythrocytes, it is important to examine whether or not other PFC blood substitutes have a similar adverse effect. The PFC in Oxypherol is PFTBA (20.0%) and the emulsifier is Pluronic-F68 (2.56%). Because of the long retention time of PFTBA in the liver and spleen, it is generally used for animal tests but not for clinical purposes. The PFC preparation that has been tested extensively in Japan and China and to a lesser degree in the United States is Fluosol-DA, 20%. Its PFC components are 14% PFD and 6% PFTPA, while 0.4% yolk phosphatidylcholine (PC) and 0.032% potassium oleate are used as co-emulsifiers in addition to 2.7% Pluronic-F68. The other components (3.0% ethyl starch as an oncotic agent, 0.60% NaCl, 0.034% KCl, 0.020% $MgCl_2$, 0.08% $CaCl_2$, and 0.21% $NaHCO_3$ as osmotic and buffering agents, and 0.18% glucose) are identical in the two types of emulsions. Fluosol-DA also has 0.80% glycerol for viscosity control, but this is not likely to affect the results as discussed below.

When Fluosol-DA was used to replace Oxypherol, it did not show a statistically significant alteration in erythrocytic deformability (Table 1, part B); in light of the findings for Oxypherol, this was an important negative result. This could be due to the presence of PC or a difference in the PFCs. To examine whether or not PC protects erythrocytes against the action of Oxypherol, we added the phospholipid to Oxypherol, sonicated the system to ensure homogeneity, and tested the emulsion in the incubation system. The results were not different from those of Oxypherol alone (Table 1, part B). Therefore, the decrease of the erythrocyte deformability must be due to different properties of the different PFCs. To ascertain this point, we made another emulsion that had the same composition as Fluosol-DA, except that PFTPA was replaced by PFTBA. This emulsion decreased the deformability of erythrocytes in the same way as Oxypherol (Table 1, part B). Finally, the emulsifier Pluronic F-68 alone was tested to make sure that it was not the cause of the decrease in erythrocytic deformability. No adverse effect was found (Table 1, part B). This negative result was not a consequence of different batches of Pluronic F-68 because the same material was ued in the PFTBA + PFD experiments. Moreover, the mean particle sizes above indicate that Oxypherol has less interfacial area available to the surface agent Pluronic than does Fluosol-DA. If mass transport of Pluronic were important in affecting the erythrocytic deformability, a smaller surface area would have less effect. This is contrary to what was observed.

From the results shown in Table 1 and the above discussion, we conclude that PFTBA causes the deformability of human erythrocytes to decrease considerably in the presence of plasma, whereas PFTPA and PFD have comparatively little effect. Many techniques have been used to assess erythrocyte deformability, although the sensitivity of various testing methods relative to the physiological deformation requirements has not been clearly established. However, at least one clinical trial with Fluosol-DA is consistent with observations of this study.[12,13]

The results of these experiments have an important implication beyond the loss of patient red cell mass because it may be related to other biological effects of the PFCs, such as their different retention times in the body and different cytotoxicities. It has recently been reported that a 25% emulsion of PFTBA is selectively cytotoxic to macrophages,[29] but it is not clear whether PFTPA and PFD have a similar effect. It is of interest to note that the effect of Oxypherol (an emulsion of PFTBA) on neutrophils[30] is much larger than that of Fluosol-DA (which contains PFTPA and PFD). Through the use of nuclear magnetic resonance, electron microscopy, and differential scanning calorimetry, we have also found that the physical state of PFTBA in phospholipid bilayers is quite different from those of the other two PFCs. Fortunately, PFTBA preparations are not used for clinical purposes. We suggest that in vitro tests, such as cytotoxicity, erythrocytic deformability, and blood compatibility, of these and other PFCs continue to be important to their development in clinical applications and should be made in parallel with animal tests. The adverse effect of one PFC does not necessarily mean that other PFCs would display similar effects, but it does emphasize the need for further testing to find the most suitable candidates for use as blood substitutes.

Donor-Derived Red Blood Cell Antibodies and Immune Hemolysis After Allogeneic Bone Marrow Transplantation

By Jill Hows, Keith Beddow, Edward Gordon-Smith, Donald R. Branch, Wayne Spruce, Irena Sniecinski, Robert A. Krance, and Lawrence D. Petz

Six cases of immune hemolytic anemia attributed to *donor*-derived red cell antibodies after allogeneic bone marrow transplantation (BMT) are reported. In 2/6 cases, severe intravascular hemolysis was seen, 6/6 required increased red cell transfusion, and 1/6 was treated by plasma exchange. All recipients were receiving cyclosporine to prevent graft-*v*-host disease. Investigations showed that in each case, the donor lacked ABO or Rho(D) red cell antigens present in the recipient. The direct antiglobulin test was positive in 6/6. Relevant serum antibody (anti-A, four cases; anti-B, one case; anti-D, one case) was first detected one to three weeks after BMT. Eluates made from recipient red cells showed the same specificity as serum antibody. Maximum hemolysis occurred nine to 16 days after BMT, suggesting that active production of antibody by "passenger" donor lymphocytes was the likely mechanism of hemolysis, rather than passive transfer of antibody in the marrow infusion. Retrospective analysis of 21 consecutive cyclosporine-treated BMT patients receiving marrow lacking ABO or D antigens present in the recipient showed that (1) 15/18 patients tested had red cell antibody production against recipient red cell antigens; (2) despite the frequent presence of antibody specific for recipient red cell antigens, only 3/21 patients developed clinically significant hemolysis; (3) clinical hemolysis could not be predicted by donor or recipient red cell antibody titers. We conclude that although red cell antibody against recipient antigens is frequently produced after minor ABO and D mismatched BMT in cyclosporine-treated recipients, only 10% to 15% of cases develop clinically significant immune hemolysis. The data presented show that the most likely source of antibody is "passenger" donor lymphoid cells.

© 1986 by Grune & Stratton, Inc.

ALLOGENEIC bone marrow transplantation (BMT) in humans involves the transfer of mature donor lymphocytes to the recipient. It is theoretically possible for transferred donor lymphocytes to produce antibodies specific for recipient red cell antigens that are lacking on the donor's own red cells. If this occurs, it could present clinically as immune hemolysis in the posttransplant period. Conceivably, complications such as renal failure could occur in association with severe hemolysis.

We report six bone marrow transplantation (BMT) cases in which the appearance of red cell antibodies was associated with clinical and laboratory evidence of immune hemolysis. The peak time for hemolysis was one to two weeks after BMT, making passive transfer of plasma antibody in the marrow infusion an unlikely cause. From the data presented, we suggest that active production of antibody by donor lymphocytes stimulated by recipient RBC antigens is the cause of the hemolysis. To determine the frequency of hemolysis due to this mechanism, we have retrospectively analyzed 97 consecutive cyclosporine-treated BMT patients from one center (Hammersmith). The association between cyclosporine and this phenomenon was strengthened by our failure to find, on retrospective analysis, a single case of immune hemolysis or donor-derived antibody production in 13 patients treated with methotrexate in the postgraft period.

MATERIALS AND METHODS

Patients

Group 1. Six patients from three transplant centers who presented clinically with immune hemolysis after BMT were investigated. Informed consent to investigations was obtained according to each of the transplant center's ethical committee guidelines. Clinical and laboratory data are shown in Table 1. Hematologic and biochemical data illustrating a typical case are shown in Fig 1. Patients 1 through 5 were transplanted from HLA-identical sibling donors and patient 6, from an HLA phenotypically matched unrelated donor. In cases 1 through 5, the donors lacked A or B antigens present on the recipients' red cells. In case 6, the patient was A Rho(D) positive and the donor A Rho(D) negative; the donor's serum contained weak anti-D at the time of the transplant. All patients received cyclosporine after BMT to prevent graft-*v*-host disease (GVHD).

Group 2. To assess the frequency of immune hemolysis, a retrospective analysis of 97 consecutive BMT patients transplanted at one center (Hammersmith) was carried out. All patients received cyclosporine in the postgraft period for the prevention of GVHD. Twenty-one patients received minor ABO or D mismatched marrow (ie, donor lacking ABO or Rh antigens present in the recipient) and were designated "group 2" patients. Within group 2, 14 patients received marrow from donors lacking recipient A or B antigens; this included cases 1 and 2 from group 1. Seven D-positive recipients received marrow from D-negative donors and included case 6 from group 1. Two patients were ABO and D mismatched. Group 2 patient charts were reviewed for evidence of immune hemolysis. Weekly blood bank records from the post-BMT period were searched for the occurrence of any positive direct antiglobulin tests (DAT). Sera from group 2 patients receiving minor ABO mismatched marrow, stored at −20 °C for up to 36 months, were tested for donor type IgG and IgM anti-A and anti-B at one and three months after BMT.

Serology

Standard serological methods were used. The DAT was performed using polyspecific antihuman globulin (AHG) reagents. In DAT-positive cases, testing with anti-C3 and anti-IgG reagents was carried out. Eluates were made by the chloroform[1] or ether[2] technique. Anti-A and anti-B were estimated by titrating the stored

sera against suitable test red cells. The agglutination titer at 20 °C was measured as well as the titer at 37 °C using anti-IgG AHG in the indirect antiglobulin test. Appropriate saline controls were performed. The IgG and IgM components of the antibodies were estimated by testing the sera before and after treatment with 2-mercaptoethanol[3] or dithiothreitol.[4] The IgM titers were measured by agglutination at 20 °C, and the IgG titers were estimated by the indirect antiglobulin test at 37 °C.

RESULTS

Group 1. Group 1 patients presented clinically with hemolysis between days 9 and 16 post-BMT (median, day 10). The results of serological investigations are shown in Table 2. The DAT first became positive at four to 22 days (median, 12) after BMT. Antibodies against the recipient's red cell antigens were first detectable nine to 15 days (median, 13) after BMT. In cases 3 through 6 inclusive eluates prepared from recipient RBCs contained antibody to antigens present on recipient red cells of the same specificity found in the serum. Table 2 also shows that the red cell antibodies were only transiently present in the sera of the ABO-incompatible cases. However, in the D-incompatible case (case 6), the anti-D titer continued to rise, reaching a level of 256 on day 70 after BMT.

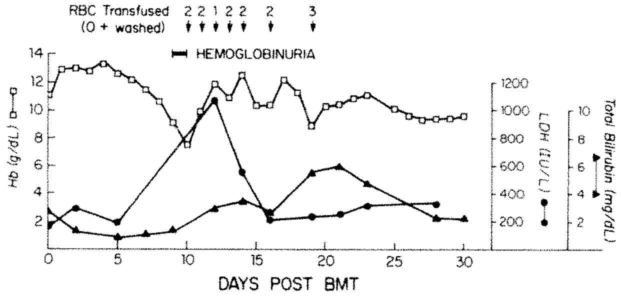

Fig 1. Case 3 from group 1. Minor ABO mismatched BMT (donor O+, recipient B+). Flow chart shows hematologic and biochemical evidence for hemolysis. Fourteen units of packed O+ cells were required to maintain the hemoglobin between day 10 and day 19 post-BMT. Note that the hemoglobin, the lactic dehydrogenase, and the total bilirubin were normal for the first five days post-BMT. During the hemolytic episode, no incompatible isohemagglutinins were infused; RBCs transfused were washed group O, platelets were group B or O washed and resuspended in fresh AB plasma.

Group 2. Relevant serological data is shown in Table 3. Six out of 16 patients receiving ABO mismatched marrow (including cases 1 and 2 from group 1) developed a positive DAT after BMT. However, only 2/6 (cases 1 and 2 in group 1) showed clinical evidence for immune hemolysis. Donor anti-A and anti-B titers pre-BMT and recipient anti-A and anti-B titers one and three months after BMT are shown. DAT-positive cases and clinical hemolysis could not be predicted by either donor or recipient antibody titers or the proportion of IgG and IgM antibody present. The antibodies were not tested with antisera specific for IgG subclasses.

Three out of the seven patients in group 2 who received D-incompatible marrow (including patient 6 from group 1) developed a positive DAT after BMT (Table 3). In all three DAT-positive cases, anti-D was detected in the serum after BMT. In one case (AG), anti-C and anti-E were also detected. Only one patient (AR) with a positive DAT due to rhesus antibodies (AR) showed clinical evidence of hemolysis (case 6 in group 1; see Tables 1 and 2).

DISCUSSION

Anti-A and anti-B production against donor red cells by residual *recipient* plasma cells after *major* ABO mismatched

Table 2. Serological Investigation of Patients Presenting With Immune Hemolysis—Group 1

Case No.	Maximum Hemolysis Day Post-BMT	ABO Group Rh Type D	ABO Group Rh Type R	DAT Positive for	Day Post-BMT DAT First Positive	Antibody in Eluate	Antibody in Serum	Day Post-BMT Serum Antibody Last Detected

DAT, direct antiglobulin test; D, donor; R, recipient; ND, not done.

*Serum antibody not detectable in subsequent follow-up.

†Anti-D titer 256; later samples not tested.

BMT is well documented.[5] Hemolysis of donor red blood cells at the time of the transplant can be prevented by removal of recipient antibodies by plasma exchange[6] or by removal of donor red cells from the marrow before infusion.[7,8]

More recently, cases of immune hemolysis occurring in recipients of *minor* ABO mismatched marrow have been reported.[9,10] Some reported episodes of hemolysis were clinically severe, and two cases of acute renal failure associated with hemoglobinuria were documented.[9] Cases of immune hemolysis occurring in patients receiving minor ABO mismatched liver[11] and kidney[12] transplants have also appeared in the literature.

We have investigated six patients from three transplant centers who presented with immune hemolysis after minor ABO or D mismatch BMT. From our data, active production of donor-derived red cell antibody is the most likely mechanism. Maximum hemolysis occurred one to three weeks after BMT, suggesting that passive transfer of antibody at the time of the transplant is an unlikely cause. None of the patients in group 1 received significant ABO-incompatible plasma in blood products (Table 1); therefore, transfusion of incompatible plasma does not account for the phenomenon.

Retrospective analysis of minor ABO mismatched BMT patients showed that only a minority (2/16) developed clinically significant hemolysis, despite the production of antibody against recipient red cell antigens in the majority of cases (Table 3). Six out of 16 patients developed a positive DAT, suggesting that in vivo red cell sensitization often occurs without signs of overt hemolysis. From data shown in Table 3, it can be seen that the onset of immune hemolysis cannot be predicted from either donor or recipient anti-A or anti-B titers. Most minor ABO mismatched patients were transfused with packed group O cells. However, the transfusion of group A or B red cells may have contributed to the severity of hemolytic episodes seen in patients 1, 2, 4, and 5 in group 1 (Table 1).

We have shown that production of donor-derived antibody specific for recipient ABO antigens is transient, with the relevant antibody being virtually undetectable by three months post-BMT (Table 3). These data are consistent with a report by Buckner et al[6] in which donor-derived antibody against recipient ABO antigens was absent or weak one year after BMT. The transient nature of donor-derived antibody against recipient ABO antigens is not understood and contrasts with the more persistent donor-derived rhesus antibodies detected. Possible mechanisms are discussed below.

The probable cause of immune hemolysis in case 6 group 1 was donor-derived anti-D. Anti-D was not detectable in the recipient's serum until 13 days after BMT and rose to a titer of 256 on day 70 after BMT. On retrospective analysis of 97 cases, seven D-positive patients received marrow from D-negative donors. Three out of seven patients (including patient 6 in group 1) produced donor-derived anti-D (Table

3). In contrast to the transient antibody production in the ABO cases, the recipients of D-incompatible marrow continued to produce anti-D for prolonged periods of up to one year after BMT. The early disappearance of donor-derived antibodies in the ABO cases may be due to high zone tolerance brought about by continued exposure of donor lymphocytes to A or B antigens in the recipients' plasma and tissues. In contrast, the rhesus mismatched BMT donor lymphocytes are only exposed to recipient rhesus antigens transiently until residual recipient red cells are eliminated from the circulation. The antigenic stimulus for donor-derived rhesus antibody production may not be strong enough to induce tolerance, but instead leads to prolonged antibody production.

The role of cyclosporine in facilitating donor-derived antibody production is uncertain. It is of interest that all cases of immune hemolysis due to donor-derived antibody so far reported have been in transplant recipients immunosuppressed with cyclosporine. Our own experience confirms this observation. We have retrospectively reviewed 13 patients transplanted in one center (Duarte) in whom methotrexate was used in the postgraft period to prevent GVHD (data not shown). We have been unable to identify a single case of immune hemolysis due to donor-derived antibody. This group of patients is now being studied prospectively to confirm our retrospective observations.

Cyclosporine is a powerful immunosuppressive agent that acts primarily by blocking proliferation of T lymphocytes in response to antigen or mitogens.[14,15] However, T lymphocyte proliferation is not impaired when presensitized lymphocytes are reexposed to antigen in the presence of cyclosporine.[16] In minor ABO mismatched BMT, the donor lymphocytes are sensitized in vivo before transfer to the recipient, so donor-derived red cell antibody production is a secondary immune response. In one D minor mismatched case (AR), we have shown that the donor was presensitized to the D antigen, with anti-D present in the donor's serum. The donor-derived anti-D produced in this recipient was, therefore, the result of a secondary immune response to the D antigen by the donor lymphocytes, analogous to the production of anti-A and anti-B in the ABO-incompatible cases described. We have no definite evidence for donor presensitization to rhesus antigens in the other two cases in which donor-derived rhesus antibodies were produced. Indeed, the donor for patient AG was a 15-year-old boy who had not been transfused, suggesting that in this case, the production of donor-derived anti-D, -C, and -E in the recipient was due to a primary immune response by the donor lymphocytes. In the third case in which donor-derived rhesus antibodies were detected (CJ), the marrow was donated by the patient's sister. Her serum did not contain detectable rhesus antibodies at the time of the transplant; however, she has two rhesus D-positive children aged 15 and 17 years. It is therefore possible that the donor became sensitized to the D antigen during pregnancy and that the production of donor-derived anti-D in the recipient was a secondary response.

Although the frequency of clinical hemolysis is low in minor ABO and rhesus mismatched BMT, it can be severe. All six group 1 patients required increased red cell support, two patients had evidence for intravascular hemolysis, and one patient required plasma exchange. Renal failure was not apparent in our patients; however, this remains a potential complication. It is not possible to predict which patients will hemolyze from monitoring donor and recipient anti-A and anti-B titers (Table 3). Our data suggest that significant hemolysis occurs in approximately 10% to 15% of cases receiving minor ABO or D mismatched transplants. To prevent exacerbation of hemolysis, recipients of minor ABO mismatched transplants should be transfused with packed or washed group O red cells. In D mismatched cases, D-negative red cells of the appropriate ABO group should be given. Platelet concentrates given to minor ABO mismatched BMT patients should be *recipient* group or group O. If group O platelets are used, transfusion of significant ABO-incompatible plasma can be avoided by using platelet preparations concentrated by centrifugation.[17] These measures will, however, not completely prevent hemolytic episodes.

In summary, we have documented the occurrence of immune hemolysis in approximately 10% to 15% of marrow transplant recipients who received minor ABO or D mismatched marrow and were treated with cyclosporine. We believe that hemolysis is due to active production of red cell antibody by donor lymphoid cells in the early posttransplant period. Antibody production may be associated with cyclosporine immunosuppression. Further work is in progress to evaluate the role of cyclosporine in the pathogenesis of this syndrome. When hemolysis occurs, it may be severe, and we have suggested a transfusion policy for patients receiving minor mismatched transplants that we hope will prevent exacerbation of the hemolysis.

Diaziquone Given as a Continuous Infusion Is an Active Agent for Relapsed Adult Acute Nonlymphocytic Leukemia

By Edward J. Lee, David A. Van Echo, Merrill J. Egorin, M.S. Balchandran Nayar, Philip Shulman, and Charles A. Schiffer

Diaziquone given as a bolus has not been effective in patients with relapsed or refractory leukemia. Because of in vitro data suggesting enhancement of diaziquone-induced cytotoxicity for human and murine leukemia cells with increased duration of drug exposure and the relatively short terminal plasma half-life of diaziquone, 49 patients (34 acute nonlymphocytic leukemia [ANLL], six chronic myelogenous leukemia in blast crisis [CML-B], five acute lymphocytic leukemia [ALL], four 2° ANLL) with leukemia were given diaziquone as a continuous infusion for seven days. The maximum tolerated dose was 28 mg/m^2/d for seven days. The dose-limiting toxicity was the duration of bone marrow aplasia (median, 49 days to >500 PMNs in responders; range, 28 to 101 days). Nonhematologic toxicity was minimal. Responses occurred only in patients with relapsed ANLL, of whom 26 were treated at effective doses. There were six complete responses (CR) (23%) and two partial responses (PR) (8%), although five of eight responders never achieved platelet counts >100,000/μL. Thrombocytopenia in these patients was felt to be a manifestation of diaziquone effect, not persistence of leukemia. The median duration of CR was 195 days (range, 88 to 860+). One patient had active CNS leukemia at the start of treatment and has had a durable (28+ month) CR in both sites of disease. Diaziquone produced prolonged aplasia in patients with secondary ANLL and CML-B (five of ten patients died aplastic), whereas patients with ALL all had regrowth of leukemia and two failed to become aplastic. The lack of significant nonhematologic toxicity and the activity in patients with relapsed ANLL render diaziquone of interest as second-line therapy or consolidation therapy in first remission for patients with ANLL.

© 1986 by Grune & Stratton, Inc.

COMBINATION CHEMOTHERAPY with an anthracycline and cytosine arabinoside has resulted in a substantial improvement in the treatment of adult acute nonlymphocytic leukemia (ANLL). Complete response (CR) rates of 60% to 80% and median survival of 18 to 30 months have been reported.[1-6] Nonetheless, the majority of patients who achieve remission, relapse, and as many as 20% fail to achieve an initial remission. Thus, a need exists for other agents that may be non-cross-resistant with the standard combinations for use either in induction or consolidation regimens.

Diaziquone (AZQ, NSC182986) is a rationally synthesized aziridinylbenzoquinone compound with good lipid solubility and low ionization allowing access to the central nervous system.[7] Diaziquone has activity in vitro against the murine leukemia cell lines L1210 and P388 and against the human leukemia cell line HL-60. In murine systems, in vivo activity against intracranially and intraperitoneally implanted tumors is seen when diaziquone is given by way of an intraperitoneal route.[8] Phase I studies using a bolus schedule in solid tumor and leukemia patients showed that diaziquone produced primarily hematologic toxicity with minimal nonhematologic side effects.[9] No responses were observed in patients with leukemia.[10-12] Pharmacokinetic studies showed that diaziquone was cleared rapidly from the plasma with a terminal half-life of approximately 30 minutes.[9,13] In vitro studies from our center demonstrated that cytotoxicity against L1210 and HL60 leukemia cell lines could be enhanced by increasing the duration of exposure of the cells to diaziquone.[14] On the basis of this demonstration of schedule-dependent enhancement of cytotoxicity, a continuous infusion trial in patients with solid tumors was carried out at the University of Maryland Cancer Center and showed no change in the known toxicities.[15] As the only toxicity of diaziquone using both bolus and continuous infusion schedules was myelosuppression, a continuous infusion phase I/II study of diaziquone was designed for patients with relapsed or refractory adult leukemia.

MATERIALS AND METHODS

Patients. Eligible patients included the following adults (age >15 years): (a) patients with de novo ANLL, either relapsed (those who had had a CR to other therapy) or refractory (those who had never achieved a CR); (b) patients with ANLL developing after a previous hematologic disorder or treatment of another malignancy who had already received combination chemotherapy with anthracycline/cytosine arabinoside (2° ANLL); (c) patients with relapsed acute lymphocytic leukemia (ALL); (d) patients with chronic myelogenous leukemia in blast crisis (CML-B).

All patients had their diagnoses confirmed by bone marrow aspirate or biopsy, or both when possible. Other eligibility criteria included recovery from previous chemotherapy or radiation therapy, a minimum life expectancy of six weeks, and adequate hepatic (bilirubin <1.5 mg/dL) and renal (creatinine <1.5 mg/dL) function. All patients had either a normocellular bone marrow with at least 30% leukemic cells or evidence of progressive leukemia. This was defined as increasing numbers of leukemic cells in the peripheral blood accompanied by signs of bone marrow failure, such as anemia, granulocytopenia, or thrombocytopenia. Written informed consent was obtained from each patient before entry onto study.

During the seven-day treatment period, all patients were examined at least daily. Complete blood counts and platelet counts were obtained daily; laboratory profiles, including hepatic and renal function, were obtained twice. After the chemotherapy period, patients had bone marrow aspirates and biopsies at weekly intervals. Hematologic, hepatic, and renal parameters were monitored on at least a weekly basis and more often as clinically indicated.

The bone marrow response determined whether a second course of diaziquone was given. If the marrow revealed increasing cellularity with persistence of leukemia after day 15, then a second course of diaziquone was given. No further chemotherapy was given if remission was achieved. Patients who failed to achieve a response to a second course were taken off study.

Responses were judged according to the following criteria: a CR was defined as an M-1 bone marrow (a normocellular marrow with <5% leukemic cells, normal maturation of the granulocyte and erythroid cell lines, and the presence of megakaryocytes) and no evidence of extramedullary disease. All patients considered to be in CR were required to have normal peripheral granulocyte counts (>1,500/μL) and to have no need for red cell or platelet transfusions. A "normal" platelet count was not required because diaziquone has been documented to cause prolonged thrombocytopenia.[16] Thus patients who were felt to have thrombocytopenia due to the drug with marrows that were otherwise M-1 were designated to be in CR. A partial response (PR) was defined as a normocellular bone marrow with fewer than 5% blasts and fewer than 30% blasts plus progranulocytes according to the criteria of the Cancer and Acute Leukemia Group B (CALGB). Nonhematologic toxicity was assessed according to the criteria of CALGB on a scale from 0 to 4.

Supportive care for all patients consists of oral prophylactic antibiotics[17]; empiric or specific parenteral antibiotics for documented or suspected infections; prophylactic platelet transfusions[18]; granulocyte transfusions for documented infections not controlled by appropriate antibiotics.[19]

Drug schedule and drug administration. Diaziquone was supplied in 10-mg vials by the Investigational Drug Branch of the National Cancer Institute (NCI) and was reconstituted with sterile *N,N*-dimethyl-acelanide and phosphate buffer for injection according to NCI recommendations. The total daily dose of diaziquone was diluted in 1,000 mL of normal saline and was prepared within six hours of use. Bottles were changed every 24 hours, since diaziquone in normal saline at the concentrations used undergoes 10% decomposition at 44 hours. The drug was administered as a continuous infusion for seven days (with two exceptions noted later) by infusion pump.

Cohorts of two to three patients were treated at doses ranging from 16 mg/m^2/d to 32 mg/m^2/d. The initial dosage was twice the maximum tolerated dose (MTD) defined in our phase I continuous infusion trial of diaziquone in solid tumor patients,[15] but 2/3 of the MTD in the phase I bolus leukemia study performed in our center.[10] Dose escalations were 4 mg/m^2/d and patients who failed to respond to their initial therapy were eligible to receive a second course at the next higher dose.

Pharmacokinetic studies. Blood samples were collected in heparinized tubes, before institution of diaziquone infusion, at 5, 15, 30, 45, 60, and 120 minutes and 24, 48, 72, 96, 120, 144, and 168 hours into the infusion and at 2, 5, 10, 15, 30, 45, and 60 minutes after termination of the infusion. Samples were centrifuged at 1,000 g for ten minutes, and the resulting plasma was removed and frozen at −20 °C until assay. Diaziquone concentrations in plasma were determined with the high-performance liquid chromatography analysis of Kelley and Siu Chong.[20] Pharmacokinetic modeling was accomplished with the MLAB Program.[21]

RESULTS

Forty-nine patients with relapsed or refractory adult leukemia were entered onto this study (Table 1). Patients with ALL had all received standard induction regimens initially and received diaziquone after other second-line treatments were unsuccessful. Diaziquone was the initial treatment in five of six individuals with CML-B; the other is described below. All patients with 2 ° ANLL were treated initially with daunorubicin and cytosine arabinoside in conventional doses. Diaziquone was the second induction regimen used in each of these patients. In patients with de novo ANLL, 11 patients had had two or more prior CRs. Diaziquone represented from the third to the tenth induction regimen given to these patients (median, three prior regimens). There were 18 patients with ANLL who had had a single prior CR. Of these, 11 received diaziquone as their initial treatment for relapse. Seven patients had undergone reinduction with either conventional-dose anthracycline/cytosine arabinoside (three patients) or high-dose cytosine arabinoside (four patients) and received diaziquone after these efforts were unsuccessful.

The number of patients treated at each dosage and the treatment outcome is presented in Table 2. No patients with ALL responded. Although all patients became hypocellular, two were never aplastic and all had regrowth of leukemia. Six patients with CML-B were treated. One was treated at 24 mg/m^2/d for seven days. This individual had a lymphoid blast crisis treated with vincristine and prednisone with an excellent response, followed by allogeneic bone marrow transplantation. Bone marrow relapse with associated hypercalcemia, lytic bone lesions and bone pain developed a few

†One patient inevaluable for response because of anaphylaxis.

months later. Diaziquone was administered and the symptoms abated only transiently. Four patients with CML-B received 28 mg/m^2/d for seven days. Three died aplastic (days 34, 43, and 65) and one had disease progression after prolonged aplasia (day 51). Because of the prolonged aplasia, the sixth patient was treated for five days at 28 mg/m^2/d and failed to achieve aplasia. Three patients with secondary ANLL were treated at a dosage of 28 mg/m^2/d for seven days. No responses were seen. All three patients became aplastic. Of these, two died aplastic (days 29 and 40) and one developed progressive leukemia. A fourth such patient was to have received 28 mg/m^2/d for seven days but is inevaluable for response due to an anaphylactic reaction within minutes of starting diaziquone. The infusion was stopped and not restarted.

Thirty-four patients with relapsed (29) or refractory (five) de novo ANLL were treated at varying doses of diaziquone. Six CRs and two PRs were seen in the relapsed ANLL group. Five patients in this group died aplastic without evidence of leukemia in the marrow at the time of death (days 15, 28, 38, 38, 44). Two patients failed to achieve aplasia (one at 16 mg/m^2/d and the other at 28 mg/m^2/d), and 14 became aplastic but had regrowth of a leukemic bone marrow. Responses occurred at dosages between 20 and 28 mg/m^2/d for seven days except for one patient who received only a five-day infusion (due to patient refusal to continue treatment although no toxicity was apparent). This individual had rapid regeneration of normal blood counts by day 28 but did not return to the hospital until two months later, when relapse was apparent. A bone marrow aspirate on day 28 showed an M-2 bone marrow with maturation in all three cell lines. No further specimens could be obtained until the patient returned with obvious progressive leukemia. The other PR occurred in an elderly patient with a regenerating bone marrow with <5% blasts and normal granulocyte counts, who died of infectious complications on day 48. All responders had slow bone marrow recovery (Table 3). Of note in these responders is that five of the eight never had platelet counts over 100,000/μL, although all but one were greater than 75,000/μL and none were transfusion dependent. This will be discussed in detail later. Thus, the overall CR rates in patients with de novo ANLL treated at what may represent effective doses ($\geq$20 mg/m^2) is 6/31, or 19% (95% confidence limits 5% to 32%). The CR rates were 6/26, or 23% (95% confidence limits 7% to 39%), if patients with primary refractory ANLL are excluded (Table 4).

Three patients had remission durations from diaziquone that exceeded the length of their prior remission durations (eight months compared with CR of six months to each of two prior regimens; 28+ months compared with 17 months for a single prior CR; 16+ months compared with eight months for a single prior CR). The second patient merits a more detailed description. She developed ANLL (FAB M-4) at age 53 and was treated with conventional-dose daunorubi-

Table 4. De Novo ANLL at Effective Doses (20–32 mg/m^2/d)

	No. of Patients	CR	PR	Resistant Disease	Died Aplastic
Relapsed	26	6	2	14	4
Refractory	5	0	0	5	0

cin and cytosine arabinoside with a CR that, with cytosine arabinoside/6-thioguanine intensification every 10 weeks, lasted for 17 months. On relapse, she was unsuccessfully retreated with daunorubicin/cytosine arabinoside in the same doses amd developed CNS leukemia during bone marrow recovery. She received cranial irradiation and intrathecal methotrexate but still had leukemic cells in her cerebrospinal fluid and focal symptoms when she was treated with diaziquone. Without further specific CNS therapy, the symptoms and findings of CNS leukemia cleared, and despite prolonged aplasia (101 days to >500 PMN, 91 days to last platelet transfusion), she achieved a complete remission and continues in unmaintained CR 32 months after initiation of diaziquone.

No responses were seen in the group of five patients who had no prior CR. Four became aplastic before developing progressive leukemia; one did not become aplastic.

Five patients received a second course of diaziquone. Two were escalated from the first two dose levels (16 to 20 mg/m^2/d, 20 to 24 mg/m^2/d); the third had a CR at 20 mg/m^2/d and was retreated at 28 mg/m^2/d after relapse. The fourth was treated initially at 28 mg/m^2/d. After an uneventful but unsuccessful course, he received a second course at 32 mg/m^2/d. The fifth patient had a transient improvement in his bone marrow after an initial course and received a second course at the same dose (28 mg/m^2/d). None of these patients responded to the second course.

Toxicity. Nonhematologic toxicity was mild (Table 5). Grade 3 gastrointestinal toxicity occurred in three patients (vomiting, two patients; mucositis, one patient), and no grade 4 toxicity was noted. Hepatic toxicity occurred in 21% of all courses and was grade 1 (ten patients) or grade 2 (one patient). Several patients had marked abnormalities in liver function late in their courses associated with infection and multiorgan system failure, usually as a preterminal event.

Of the 11 patients who died aplastic, ten died of infectious consequences and one alloimmunized patient died of an intracranial hemorrhage on day 15. There were no drug-related toxicities involving the central nervous, renal, cardiac, or pulmonary systems. One patient had an anaphylactic reaction to diaziquone within minutes of starting the initial infusion. She had a history of multiple drug allergies and had had an anaphylactic reaction to vitamin K two weeks before institution of diaziquone therapy. Her reaction (bronchospasm, flushing, hypotension) was successfully treated without complications. She received no further diaziquone.

Table 5. Nonhematologic Toxicity

Dosage (mg/m^2/d)	No. of Patient Courses	Vomiting	Mucositis	Hepatic
16	3	2	0	0
20	3	1	0	0
24	3	1	0	0
28 × 5 d	2	0	0	1
28 × 7 d	39*	16 (2)	8 (1)	10
32	3	0	1	0
	53			

All grade 2 or less except those in parentheses (grade 3 or 4).

*One patient not included here developed anaphylaxis within minutes of initiation of diaziquone therapy.

Three courses of therapy were given at 32 mg/m^2/d for seven days. In one patient with ANLL, bone marrow necrosis occurred. This individual had, at the outset, a performance status of 3, significant bone pain with a markedly hypercellular bone marrow, extramedullary disease (large subcutaneous chloromas), and infection. After the initiation of treatment with diaziquone, his bone pain resolved within 24 hours and his chloromas resolved within a week. Bone marrow aspirates and biopsies from multiple sites showed necrotic material throughout his course. No regeneration of normal marrow elements or leukemic cells occurred and death occurred after 38 days. A second individual with ALL also developed bone marrow necrosis but thereafter developed progressive leukemia after 30 days. A third patient had an uncomplicated but unsuccessful course at 32 mg/m^2/d after an initial course of diaziquone at 28 mg/m^2/d.

Hematologic toxicity was profound. All patients required red blood cell and platelet transfusions. The dose-limiting toxicity of diaziquone was the duration of aplasia (median, 49 days to >500 PMN for responders; range, 27 to 101). In view of this and the occurrence of bone marrow necrosis in two of three patients at 32 mg/m^2 for seven days, no further courses at dosages above 28 mg/m^2/d for seven days were given.

Pharmacokinetic studies. Steady-state plasma concentrations of diaziquone in 11 patients treated with 28 mg/m^2/d for seven days were 101 ± 10 ng/mL (mean ± SEM; range, 54 to 150 ng/mL) and were achieved 45 minutes after initiating treatment. At the cessation of the infusion, plasma concentrations of diaziquone declined by monoexponential decay with a mean half-life of 47.7 ± 11.4 minutes. Little variability was seen in steady-state concentrations in individual patients.

DISCUSSION

Previous studies of diaziquone given as a bolus have not demonstrated activity either in ANLL or in ALL.[10–12] Fifty-seven patients (36 with ANLL) have been treated in these studies with no CR or PR reported. On the basis of observations of enhanced cytotoxicity against leukemia cell lines with increased duration of exposure to diaziquone at our center, a continuous infusion trial has been conducted. When given by this method, a significant level of activity was seen in patients with de novo ANLL who had achieved a prior remission. In this group, 26 patients were treated at doses that produced responses, and six achieved CR (23%) and two achieved PR (8%) for an overall response rate of 31% (8/26) (Table 5). This strongly suggests that the change in drug scheduling was responsible for these improved results. These response rates compare favorably with response rates for other new agents, such as m-AMSA,[22] homoharringtonine,[23] and mitoxantrone.[24]

Five of the responders failed to regenerate platelet counts in excess of 100,000/μL. Examination of several bone marrows in each of these patients revealed fewer than 5% blasts, normal myeloid and erythroid maturation, and diminished numbers of megakaryocytes. One responder had biopsy-proven chronic active hepatitis that antedated diaziquone, splenomegaly, and a platelet count of 88,000/μL 16 months after treatment. Because diaziquone is associated with prolonged thrombocytopenia in patients with solid tumors, it is our feeling that failure to regain a normal platelet count is drug-related and not evidence of persisting leukemia. In the patient who had the best response (28+ months), a year passed before the platelet count became normal (>150,000); currently, it is between 250,000 and 300,000/μL. Thus, despite the lack of a normal platelet count, we feel that these individuals with otherwise normal-appearing bone marrows, diminished megakaryocytes, and no transfusion requirement should be considered CRs.

Prolonged bone marrow aplasia was seen in all patients with CML-B and 2 ° ANLL treated for seven days, but no responses occurred. Of the eight patients treated for seven days, five died aplastic. In these two groups with possibly depleted stem cell pools, it may be necessary to reduce the dosage of diaziquone. In patients with ALL, the failure to achieve aplasia in conjunction with the toxicity at 32 mg/m^2/d make it likely that diaziquone will not have much impact on the treatment of ALL. Although an insufficient number of patients are reported to exclude activity, no responses were seen.

Nonhematolgic toxicity was minimal. Anaphylaxis was seen in one patient. Although this complication has been reported,[25] it has, in the past, only been associated with individuals who had prior exposure to the drug. This patient had no such prior exposure, although a recent reaction to a drug with similar structure and a history of multiple drug allergies was present. Diaziquone should be administered with caution to patients with similar histories.

Bone marrow necrosis occurred in two of three patients given 32 mg/m^2/d. Although other causes exist that may cause this complication, such as leukemia and infection,[26] the prolonged duration of aplasia at 28 mg/m^2/d suggests that further dose escalations will not be possible in patients with ANLL. Approximately ¼ of the patients given full-dose diaziquone developed mild mucositis. Symptoms were limited to the mouth. Of note is the lack of significant hepatic toxicity. In previous reports involving diaziquone, two patterns of hepatic abnormalities were described. One consisted of a transient minimal elevation of transaminases or bilirubin. The other consisted of marked abnormalities occurring late in the course associated with systemic infection. The first pattern is likely to be drug-related but of little clinical consequence, whereas the second pattern is not clearly related to diaziquone and is generally a preterminal event. Both patterns were observed in the patients in this study, yet two patients with biopsy-proven chronic active hepatitis received full-dose diaziquone (28 mg/m^2/d for seven days) without worsening of hepatic function. One of those individuals died aplastic (day 42). The other achieved a CR with bone marrow recovery after six weeks similar to other responders.

Several patients, responders and nonresponders alike, had benign courses with minimal or no infectious complications and were managed as outpatients for much of their course. This lack of early complications is unique to diaziquone and unlike any other phase II agent studied in relapsed leukemia, such as anthracycline analogues,[24] high-dose cytosine arabinoside,[27] homoharringtonine,[23] or etoposide.[28] The prolonged period of granulocytopenia and infectious consequences represents the dose-limiting toxicity.

The steady-state plasma concentration of diaziquone achieved in this study agreed with those predicted from the relationship:

$$\text{Steady-state concentration} = \frac{\text{Rate of infusion}}{\text{Total body clearance}}.$$

From the rate of infusion of 28 mg/m^2/d and the total body clearance values of 517 ± 159 mL/min defined in the studies of intravenous bolus diaziquone,[9,13] plasma steady-state diaziquone concentrations of 49 to 92 ng/mL would be expected. Not only are the calculated values similar to those actually measured in our patients (range 54 to 150 ng/mL), but they are also in the range of diaziquone concentrations ($IC_{50} \approx 100$ ng/mL) shown by us to inhibit the in vitro growth of human and murine leukemia cells.[14] In addition, the favorable response seen in the only patient with leptomeningeal leukemia is compatible with the observation that administration of diaziquone by continuous infusion to dogs produces drug concentrations in the CNS equivalent to those in the plasma.[29]

The plasma terminal half-lives of diaziquone measured in patients treated in this study are somewhat longer than the 31- and 33-minute half-lives observed after intravenous bolus administration of diaziquone.[9,13] It is possible that the slightly longer half-lives and somewhat higher steady-state diaziquone concentrations observed in our patients reflect some subclinical hepatic effect, such as reduced metabolism or clearance associated with prolonged infusion of high concentrations of diaziquone. On the other hand, it may not be necessary to implicate any such alterations, since there is reasonable agreement between the pharmacokinetic values measured and defined in this study and those described previously in studies using strikingly different doses and schedules.

The lack of extramedullary or liver toxicity make diaziquone an interesting drug to combine with another agent of established activity in the treatment of ANLL. Indeed, both the duration of response and the occurrence of a durable CR in a patient who had failed to achieve remission after reinduction with daunorubicin and cytosine arabinoside render diaziquone of interest as either second-line reinduction therapy or as consolidation after initial remission because of the potential lack of cross-resistance. However, in view of the prolonged duration of bone marrow aplasia, it will be necessary to reduce either the dosage or the duration of infusion of diaziquone for use in combination. A trial of diaziquone and amsacrine in combination is in progress at our center.

The demonstrated activity and mild nonhematologic toxicity also raise the possibility of using diaziquone in preparative regimens for bone marrow transplantation for patients with ANLL. Resistant leukemia remains a major problem in patients transplanted in relapse or first or second remission who have at least a 15% chance of developing leukemia after transplantation.[6] As bone marrow necrosis occurred when the dose of diaziquone was increased, it may not be possible to treat patients at higher dosages than that defined in this study. Nonetheless, it should be noted that alternative explanations for bone marrow necrosis existed. Studies to define the role of diaziquone in this setting would be of considerable interest.

Modulation of Human Neutrophil Effector Functions by Monoclonal Antibodies Against Surface Membrane Molecules of 94,000 and 180,000 Molecular Weight

By Charles H. King, Charles A. Peck, Cynthia S. Haimes, J.W. Kazura, Philip J. Spagnuolo, John A. Sawyer, G. Richard Olds, and Adel A.F. Mahmoud

Function-related antigens on the neutrophil (PMN) surface were identified using two newly developed PMN-specific mouse monoclonal antibodies. These IgG antibodies, designated Ab 1-14 and Ab 1-15, were selected for detailed study after initial testing revealed their significant inhibition of PMN superoxide generation in response to *N*-formyl-Met-Leu-Phe (FMLP) (64% for 1-14 and 64% for 1-15; $P < .05$). In further experiments, Ab 1-14 augmented PMN adhesion (by 111%; $P < .01$) and degranulation (by 52%; $P < .05$) in response to FMLP, while Ab 1-15 inhibited these responses by 42% and 29%, respectively ($P < .05$). Ab 1-14 reduced PMN chemotaxis in response to FMLP by 37% ($P < .02$), and unlike Ab 1-15, Ab 1-14 significantly reduced unstimulated PMN binding of complement-coated sheep red blood cells. Ab 1-14 and Ab 1-15 significantly reduced PMN superoxide production in response to phorbol myristate acetate (PMA) (14% and 23%, respectively; $P < .05$). Whereas 1-14 was found to increase PMA-induced cell degranulation significantly (175%), Ab 1-15 did not alter degranulation response to PMA. Immunoprecipitation showed that Ab 1-14 and Ab 1-15 recognized respective surface antigens of 94,000 mol wt and 130,000 to 180,000 mol wt. Our findings suggest that the surface molecules identified by these two monoclonal antibodies play a significant role in neutrophil activation by both FMLP and PMA.

© 1986 by Grune & Stratton, Inc.

CELL SURFACE INTERACTION with external stimuli is required for in vitro activation of neutrophil (PMN) functions, including chemotaxis, adhesion, and secretion.[1-8] Because chemical and biochemical techniques have been unable to isolate single, well-defined functional molecules from complex PMN surface structures, the roles played by various surface components in the PMN activation sequence remain poorly defined.

In the present study, monoclonal antibodies were used to identify individual PMN surface structures and to study the role of these molecules in PMN activation. We developed antineutrophil-specific murine monoclonal antibodies and screened these reagents for modulation of PMN functions in vitro. Two anti-PMN monoclonal antibodies were identified that significantly altered PMN function in studies of cell adherence, locomotion, superoxide generation, and degranulation. Binding of individual antibodies to cell surface antigens was found to result in either specific inhibition or enhancement of various stimulated cell functions. Immunoprecipitation and polyacrylamide gel electrophoresis were then used to identify the cell surface antigens recognized by these antibodies.

MATERIALS AND METHODS

Purification of human leukocytes. Human peripheral blood neutrophils and mononuclear cells were isolated from heparinized blood of healthy volunteers by Ficoll-Hypaque (Pharmacia Fine Chemicals, Piscataway, NJ) density centrifugation.[9] Mononuclear cells were removed from the serum-gradient interface, while PMN were recovered from the cell pellet by dextran sedimentation and hypotonic lysis of contaminating erythrocytes. The resulting preparation contained 97% to 99% neutrophils and 1% to 3% mononuclear cells as assessed by microscopic inspections of Wright-stained smears. Viability was 95% to 97% by trypan blue exclusion. Peripheral blood eosinophils were purified by centrifugation of buffy coat cells over a discontinuous metrizamide gradient as previously described.[10] This technique yielded ≥90% eosinophils, with the remaining cells being PMN. Viability was >95%.

Mononuclear cells were further fractionated into adherent cells (90% monocytes, 10% lymphocytes) and nonadherent cells (97% lymphocytes, 3% monocytes) by incubation for one hour in plastic plates at 37 °C.[11] The nonadherent cells were fractionated into erythrocyte rosetting (E^+) and nonrosetting populations by incubation with sheep red blood cells and repeat centrifugation on Ficoll-Hypaque.[12] After RBCs were removed from the E^+ cells by lysis (in 0.85% ammonium chloride), the resultant population was found to be 95% lymphocytes with 97% viability. In studies of the specificity of antibody binding to different leukocyte subpopulations, "adherent cells" were used as monocytes and E^+ were used as lymphocytes.

Immunization and cell hybridization. Eight- to 10-week-old female BALB/c mice (Jackson Laboratories, Bar Harbor, Me) were immunized by intraperitoneal injection of 5×10^7 purified human neutrophils in complete Freund's adjuvant (Difco, Detroit). Initial immunization was followed by booster doses of 2.5×10^7 PMN in incomplete Freund's adjuvant at 14 and 28 days. One week later animals were bled and their sera screened for antineutrophil antibodies. Seropositive animals were injected intravenously with 1×10^7 human PMN; three days later their spleens were removed and single-cell suspensions were prepared.

Cell fusion was carried out according to the procedure of Kohler and Milstein.[13] Spleen cells (10^8) were fused with 2×10^7 P3NS-1 myeloma cells (ATCC #TIB18) in 35% polyethylene glycol (Sigma Chemical, St Louis) and 5% dimethyl sulfoxide (Fisher Chemical, Fairlawn, NJ) in RPMI 1640 (M.A. Bioproducts, Walkersville, Md).[14] Fused cells were incubated in RPMI containing 15% fetal calf serum (Hyclone, Logan, Utah) and hypoxanthine, aminopterin, and thymidine (HAT; reagents supplied by Sigma) at 37 °C in a humidified 5% CO_2 atmosphere. After 14 days the medium was changed to HT medium. Seven to 14 days later the supernatants from wells containing growing hybridoma cells were screened for the presence of antineutrophil antibody.

Screening of culture supernatants for monoclonal antibodies against PMN. Antineutrophil antibodies were detected by solid-phase radioimmunoassay using intact fixed cells. PMN (10^5) or other purified leukocytes were fixed to microtiter plates (Immulon

Removawell Strips, Dynatech, Alexandria, Va) in the presence of glutaraldehyde (grade I, Sigma, kept at −20 °C until use) and 0.1% bovine serum albumin (RIA Grade, Sigma). Five percent rabbit serum in phosphate-buffered saline (PBS, pH 7.4) was then added to saturate nonspecific protein binding sites. The wells were extensively washed with PBS, and then 100 μL of hybridoma supernatant was added and incubated with the fixed cells for two hours at 37 °C. The plates were washed with PBS, and 50 μL of ^{125}I-labeled goat anti-mouse immunoglobulin were added (2×10^5 cpm; New England Nuclear, Boston). After incubation for two hours at 4 °C, the wells were washed three times with buffer, and the individual wells broken apart and counted. To determine the class and subclass of antibodies, immunodiffusion assays of hybridoma supernatants against antimouse IgM, IgA, IgG_1, IgG_{2a}, IgG_{2b}, and IgG_3 antisera (Research Products, Mount Prospect, Ill) were performed.[15]

Measurements of PMN function and effect of monoclonal antibodies. The effects of anti-PMN monoclonal antibodies on various cellular functions were examined in vitro using standard assays. These included (a) adherence to tissue culture plastic,[16] (b) PMN rosetting with IgG and IgM/complement-coated sheep red blood cells,[17] (c) PMN chemotaxis under agarose,[18] (d) superoxide generation by cytochrome C reduction assay,[19] and (e) PMN degranulation as measured by cell release of lysozyme and β-glucuronidase enzymes[20,21] with control for cell release of the cytoplasmic enzyme lactic dehydrogenase.[22] Cell stimuli included *N*-formyl-Met-Leu-Phe (FMLP; Sigma), phorbol myristate acetate (PMA; Sigma), zymosan-treated serum, and complement-opsonized zymosan.[1]

For these experiments, antibody-pretreated cells were prepared by incubating 10^7 PMN in 1 mL of endotoxin-screened (Pyrogent, Mallinkrodt, St Louis) hybridoma supernatant for ten to 30 minutes at 4 °C. Cells were then washed twice in Hanks' balanced salt solution without calcium or magnesium (HBSS, KC Biological, Lenexa, Kans) and added to complete medium (RPMI) or complete HBSS in experimental assays. Control experiments were performed using cells pretreated with P3NS1 (nonsecretory myeloma) supernatant or with supernatant containing irrelevant IgG monoclonal antibody.

For some cell function experiments, and for immunoprecipitation, purified monoclonal antibodies were prepared from malignant hybridoma ascites fluid obtained by injecting 10^8 hybridoma cells into the peritoneal cavities of BALB/c mice previously primed with 2, 6, 10, 14 tetramethyldecane.[23] Ascites fluid was harvested at 14 to 21 days, filtered, and chromatographed on DEAE affigel blue (Bio-Rad Labs, Richmond, Calif).[24] Fractions containing antibody, as determined by sodium dodecyl sulfate-polyacrylamide electrophoresis (SDS-PAGE) and radioimmunoassay (RIA), were pooled and IgG concentrated by lyophilization and 35% saturation ammonium sulfate precipitation. Purity was assessed by SDS-PAGE and immunodiffusion. $F(ab')_2$ fragments were prepared by pepsin digestion of purified IgG as previously described.[25]

Identification of PMN surface proteins detected by monoclonal antibodies. Cell surface proteins were labeled with ^{125}I by the iodogen (Pierce Chemical Co, Rockford, Ill) technique.[26,27] Purified PMNs (50×10^6) were washed twice in PBS and resuspended in 1 mL PBS. In some experiments, PMNs were then incubated in PBS containing 0.005 mol/L diisopropylfluorophosphate (DIFP, Sigma); after ten to 30 minutes' incubation with DIFP on ice, cells were washed and incubated 30 minutes in PBS before labeling to remove excess unreacted DIFP. Iodogen (10 μg) was dissolved in chloroform and dried onto the surface of a 20-mL glass scintillation vial. The vessel was first rinsed with PBS, and then the treated PMN were added along with 200 μCi carrier-free sodium ^{125}iodide (100 mCi/mL, New England Nuclear). After 30 minutes' incubation on ice, the cells were washed three times in cold PBS to remove unbound isotope and resuspended in 250 μL of extraction buffer (1% Triton X-100 [Fisher] containing 10 mmol/L iodoacetic acid/10 mmol/L phenylmethylsulphonylfluoride [Sigma]). Cells and detergent were vortexed every ten minutes, and after 30 minutes' incubation at 0 °C, the tubes were spun at 200 g for 20 minutes to remove nuclei and cellular debris.

In immunoprecipitation studies, 20 μg of ^{125}I-labeled cell extract protein was incubated with 200 μg purified monoclonal IgG (1-14, 1-15, or control). After two hours' incubation at 37 °C, 200 μg of the precipitating goat antimouse IgG (New England Nuclear) was added, and the antigen/antibody/antibody mixture was incubated overnight at 4 °C. The resulting precipitate was pelleted at 500 g for ten minutes at 4 °C and then washed three times with hypotonic buffer (0.1%, NP-40/0.1 mol/L NaCl/0.1 mol/L Tris, pH 7.4). The precipitated proteins were then reduced and denatured in buffer containing 5% 2-mercaptoethanol (Sigma) and 2% SDS (Bio-Rad) in 0.125 mol/L Tris, pH 6.8, and separated electrophoretically on an SDS-polyacrylamide slab gel. Radioactive bands on dried gels were identified by autoradiography.

Data analysis. Statistical significance of differences between experimental groups was determined by Student's *t* test for unpaired and paired data.

RESULTS

Production and screening of anti-PMN monoclonals. One hundred hybridoma clones of NS1 myeloma cells fused with splenocytes of PMN-immunized mice demonstrated regular growth and were screened for antineutrophil activity. Of these, 23 were positive by RIA against fixed human PMNs. Specificity of PMN recognition was determined by comparison of RIA-measured antibody binding to PMNs *v* other types of purified peripheral blood leukocytes. Clones 1-14 and 1-15 were selected for further study on the basis of apparent anti-PMN specificity (Table 1). By double immunodiffusion, antibody 1-14 was determined to be IgG_{2b}, while antibody 1-15 was found to be IgG_1. Subsequent PMN functional studies were performed using the culture supernatants produced from twice subcloned hybridoma cell lines.

Effects of monoclonal antibodies on superoxide generation and degranulation. Monoclonal antibody effects on PMN activation were studied initially by assay of PMN superoxide generation in response to 0.1 μmol/L FMLP and 10 ng/mL PMA (Table 2). After preexposure to Ab 1-14 containing supernatant, PMN release of O_2^- anion in response to FMLP was decreased by 64% (40 nmol/10^7

Lymphocytes	3,059	3,254	2,292
Monocytes	2,200	3,200	2,215

Purified human leukocytes fixed to plastic wells were exposed to hybridoma supernatants containing monoclonal IgG. After incubation and removal of excess antibody by sequential washes, antibody binding was quantified by a second incubation with ^{125}I-$F(ab')_2$ fragments of sheep antibody against mouse IgG. Mean data are reported from three experiments.

*Significant difference from control IgG ($P < .05$) by paired *t* test.

Table 2. Effects of Monoclonal Antibodies 1-14 and 1-15 on PMN Degranulation and Superoxide Production in Response to FMLP and PMA

	PMN Preexposure	Degranulation* (% Total Cell Enzyme Released)		Stimulated O_2^- Production† (Net nmol O_2^- Released Over 10 min/10^7 PMN)
		Lysozyme	β-Glucuronidase	
Unstimulated PMN	Control IgG	3 ± 1	2.9 ± 0.3	Baseline

	Ab 1-15	5 ± 2	2.7 ± 0.7	170 ± 20 (−23%)

*Mean ± SE granule release for five experiments assayed as enzyme content in cell supernatant after 30 minutes' incubation/enzyme content from 10^6 lysed PMN. Control for cell lysis was performed by measurement of the cytoplasmic enzyme lactate dehydrogenase (LDH). LDH release was ≤5% in all experiments.

†PMN release of superoxide anion measured as superoxide dismutase inhibitable reduction of cytochrome C (19) mean ± SE for five (PMA) or eight (FMLP) experiments.

‡Significant difference from response in control IgG ($P < .05$).

PMN/10 min *v* 110 nmol/10^7 PMN/10 min for PMNs preincubated in irrelevant monoclonal IgG, $P < .05$). Preincubation with Ab 1-15 likewise decreased PMN O_2^- response to FMLP by 64%. Furthermore, PMN superoxide release in response to PMA was reduced 14% by Ab 1-14 and 23% by Ab 1-15. Neither antibody produced inhibition of PMN superoxide release in response to zymosan-activated serum or to serum-opsonized zymosan (data not shown).

We next examined the effect of Ab 1-14 and Ab 1-15 on PMN degranulation response to FMLP and PMA. Incubation with monoclonal antibody 1-14 significantly increased degranulation in response to 1 μmol/L FMLP (Table 2); release of cell lysozyme was increased 52% ($P < .01$). Augmentation of PMA-induced degranulation also was noted (Table 2). In contrast, antibody 1-15 decreased cell granule release in response to FMLP, resulting in a 29% ($P < .05$) decrease in β-glucuronidase release. Viability assays and control assays for release of the cytoplasmic enzyme lactic dehydrogenase showed that the effects of antibodies 1-14 and 1-15 were not due to cytotoxicity. It was noted, however, that Ab 1-14 did significantly increase lysozyme release by unstimulated PMNs (6% of total cell enzyme release *v* 3% for control IgG ($P < .05$).

Effects of monoclonal antibodies on chemotaxis, adherence, and binding of opsonized particles. The ability of normal peripheral blood neutrophils to migrate in response to 0.1 μmol/L FMLP was diminished by monoclonal antibody 1-14. By contrast, incubation of PMNs in monoclonal 1-15 or control irrelevant IgG monoclonal had no effect on chemotaxis. In four separate experiments, the mean chemotactic index of cells incubated in the absence of antineutrophil antibody was 2.2 ± 0.2. Cells incubated in monoclonal 1-14 had a significantly lower chemotactic index (1.4 ± 0.1, $P < .02$) in response to FMLP. This decrease was found to be due to a specific 42% decrease in directed migration toward FMLP and not an effect on random cell migration.

Neutrophil adherence to plastic was significantly augmented by monoclonal antibody 1-14 under both unstimulated and FMLP-stimulated conditions. Preincubation of PMNs with antibody 1-14 increased unstimulated PMN adherence to tissue culture plastic by 115% (Table 3, $P < .05$) and FMLP-stimulated adherence by 111% ($P < .01$). In contrast, preincubation of cells with antibody 1-15 decreased unstimulated adherence by 64% ($P < .05$), and it also decreased FMLP-stimulated adherence (Table 3). There was no inhibition of PMA-stimulated cellular adherence in the presence of monoclonal 1-15.

In studies of cell adhesion to opsonized substrate, preincubation of PMNs in antibody 1-14 significantly reduced cell rosetting with IgM/complement-sensitized erythrocytes (74% decrease, $P < .01$; see Table 3). Ab 1-14 had no effect on cell rosetting with IgG-sensitized sheep erythrocytes, and preincubation with antibody 1-15 had no effect on PMN rosetting with either complement- or IgG-opsonized targets.

Effects of 1-14 and 1-15 purified IgG and F(ab')$_2$ fragments on PMN function. To determine the specificity of antibody effects on stimulated PMN function, further superoxide generation experiments were performed using highly purified 1-14 and 1-15 antibodies obtained from mouse hybridoma ascites. Alone, purified 1-14 and 1-15 IgG preparations were not stimulatory for PMNs. However, these purified antibodies, like the previously studied antibody-containing supernatants, produced significant inhibition of cell superoxide response to 0.1 μmol/L FMLP and 10 ng/mL PMA in a dose-dependent fashion: significant inhibition of PMN-induced superoxide generation was seen for IgG concentrations of 25 μg/mL (9% to 10% inhibition, $P < .05$) up to 500 μg/mL (60% to 80% inhibition, $P < .01$). F(ab')$_2$ fragments of 1-14 and 1-15 were also found to mediate significant inhibition of stimulated PMN superoxide production. In four separate experiments, 25 μg/mL of 1-15 F(ab')$_2$ reduced mean cell response to FMLP from 78 ± 11 nmol/10^7 cells/10 min [in the presence of control F(ab')$_2$] to 54 ± 12 nmol/10^7 cells/10 min, or by 34% ($P < .05$ by paired *t* test). Mean cell responses to PMA were reduced from 381 ± 22 (control) to 320 ± 36 nmol/10^7 cells/10 min, or by

Table 3. Effects of Monoclonal Antibodies 1-14 and 1-15 on PMN Adherence to Plastic and Binding of Opsonized Red Blood Cells

	PMN Preexposure	Adherence to Plastic (cells/well × 10^{-3})	Binding to IgSRBC	Binding to C'-SRBC (% rosetting PMN)
Unstimulated PMN	Control IgG	14 ± 1	76 ± 4	27 ± 4
	Ab 1-15	5 ± 1* (−64%)	82 ± 2 (+8%)	22 ± 4 (−19%)
	Control IgG	68 ± 24	76 ± 4	27 ± 4
	Ab 1-14	146 ± 41* (+115%)	78 ± 2 (+3%)	7 ± 1† (−74%)
FMLP-stimulated	Control IgG	67 ± 8	NT	NT
	Ab 1-15	39 ± 3* (−42%)		
	Control IgG	159 ± 38	NT	NT
	Ab 1-14	336 ± 68* (+111%)		

After ten minutes' preincubation with specific monoclonal or control supernatant, adherence to plastic was assayed by PMN incubation in tissue culture wells for one hour at 37 °C. Nonadherent cells were removed by gentle washing and adherent cells recovered and enumerated on a particle counter. Results reported as mean ± SE for three to seven assays. Because of interdonor variation in PMN adhesive response to plastic, mean control data for each experimental series are reported. To assay PMN binding of opsonized RBC purified human PMNs were incubated for 15 minutes at 37 °C with SRBC opsonized with either rabbit antisheep RBC IgG or rabbit antisheep RBC IgM/human serum. Rosetting was scored visually as >3RBC adherent/PMN, and results are reported as % rosetting PMN (mean ± SE) for three experiments. NT, not tested.

*Significant difference from PMN response with control IgG ($P < 0.05$), by Student's paired t test.

†$P < .01$.

16% ($P < .05$). In the same experiments, 25 μg/mL of 1-14 $F(ab')_2$ fragments also significantly reduced mean FMLP response to 57 ± 14 nmol/10^7 cells/10 min (27% decrease, $P < .01$) and PMA response to 333 ± 26 nmol/10^7 cells/10 min (13% decrease, $P < .02$).

Apparent molecular weights (mol wt) of the antigens recognized by monoclonals 1 to 14 and 1 to 15. The antigens detected by purified monoclonal antibodies 1-14 and 1-15 were characterized by immunoprecipitation of antigens from ^{125}I-labeled PMN membrane extracts. Proteins were separated by electrophoresis on reducing SDS-polyacrylamide gel. The results are shown in Fig 1. Antineutrophil antibody 1-14 recognized a surface protein of apparent mol wt 94,000. This band was not seen in precipitates formed with an irrelevant monoclonal IgG (control). Initial experiments indicated that the PMN antigen recognized by Ab 1-15 was variable in apparent mol wt (from 125,000 to 180,000); in later experiments, however, 30-minute pretreatment of PMNs with the protease inhibitor DIFP was found to result in reproducible Ab 1-15 immunoprecipitation of a molecule of 150,000 to 180,000 mol wt. Immunoprecipitation studies using either Ab 1-15 or Ab 1-14 with extracts of other peripheral blood cell types did not show ^{125}I-labeled protein precipitation. Using excess antibody, pre-precipitation of the 1-14 antigen from cell extracts did not remove the 1-15 antigen and vice versa.

DISCUSSION

In order to obtain specific reagents for use in structure-function analysis of the PMN surface, we screened newly developed anti-PMN monoclonal antibodies for their ability to modify PMN activation response in vitro. In initial study of hybridoma supernatants, we used a RIA against intact PMNs to increase chances of finding antibodies directed against PMN surface structures. After the anti-PMN specificity of these antibodies was established by RIA, their recognition of individual PMN surface structures was defined in immunoprecipitation studies. In assays of PMN function in vitro, two anti-PMN clones were found to produce antibodies that significantly altered cell function. Exposure to antibody 1-14 increased both PMN adherence and degranulation response in vitro but decreased directed migration of cells. Furthermore, Ab 1-14 reduced superoxide generation in response to FMLP and PMA and decreased the ability of PMN to rosette with complement-coated red cells, without affecting Fc-mediated binding or cell activation by complement-opsonized zymosan. In contrast, PMN exposure to antibody 1-15 reduced cell function in assays of adherence, chemotaxis, degranulation, and superoxide generation.

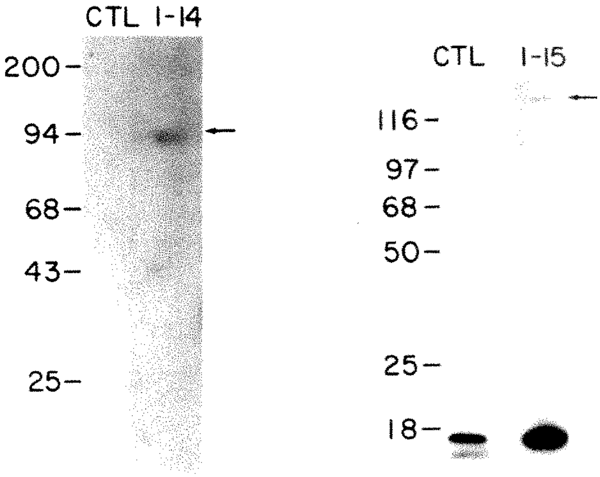

Fig 1. PMN antigen immunoprecipitation by monoclonal antibodies 1-14 and 1-15. Solubilized ^{125}I-labeled PMN surface proteins were incubated with Ab 1-15 or 1-14 for two hours at 37 °C and then precipitated with a goat antimouse IgG for 18 hours at 4 °C. Washed precipitates were reduced and denatured in 2-mercaptoethanol/SDS buffer and proteins separated on a 7.5% or 10% SDS-polyacrylamide slab gel. Autoradiography of the gel indicates specific recognition of a 150,000-mol wt molecule by antibody 1-15 (right-hand panel) and a 94,000-mol wt molecule by antibody 1-14 (left-hand panel). Lanes marked CTL indicate results for control monoclonal IgG in each experiment; migration of mol wt standards is indicated at the left of each panel.

Ab 1-15, however, had no effect on PMN binding of opsonized targets.

By these criteria, we developed two monoclonal cell lines that make antibodies with specificity for cell function-related neutrophil surface molecules of 94,000 and 150,000 to 180,000 mol wt. The individual antibodies, 1-14 and 1-15, had differing effects on PMN activation in response to FMLP and PMA; cell exposure to Ab 1-14 promoted cell activation in some assays and inhibited cell function in others. Exposure to Ab 1-15 either inhibited cell function or had no effect on cell response. Purified $F(ab')_2$ fragments of 1-14 and 1-15 were shown to mediate significant inhibition of PMN superoxide generation in response to FMLP and phorbol diester. This finding makes it unlikely that the function-modulating effects of 1-14 and 1-15 are due to cell activation or prestimulation by aggregating IgGs or to the specific effects of cell binding of the Fc portion of these IgG molecules. In our studies, we did not further investigate the possibility that isotype variations between 1-15 (an IgG_1) and 1-14 (an IgG_{2b}) outside the Fc region might account for their divergent function-altering effects. If isotype differences in cell recognition or binding are significant, our control IgG, an IgG_1, may not have been an appropriate control for antibody 1-14. Final resolution of the question of isotype influence awaits the development of new monoclonals of different isotypes that recognize the same antigen epitopes as antibodies 1-14 and 1-15.

Previous studies (Table 4) have also noted divergent affects of various monoclonal antibodies on PMN function in vitro. Cotter et al[28] and Beatty et al[29] have described antibodies, NCD 3 and 60.3, that inhibit PMN chemotaxis to FMLP. Martin et al[30] have developed a monoclonal that inhibits PMN oxidative metabolism induced by diverse stimuli. Anderson et al[8] mention unpublished data indicating that the monoclonal Mol inhibits PMN superoxide response to opsonized zymosan, and Painter et al[31] have also published preliminary data describing differential PMN inhibition and activation by three anti-PMN monoclonal antibodies. By contrast, Stevenson et al[32] have described two antineutrophil monoclonal antibodies that do not alter cell function. With the exception of Mol and 60.3, previous studies of antibody-mediated cell inhibition have not defined the surface antigens recognized by the monoclonal antibodies studied. This limits our ability to compare Ab 1-14 and 1-15 with these other antibodies.

The significance of membrane structures in PMN effector response to inflammatory stimuli has been evaluated by several groups.[33-39] Surface receptors have been described for the Fc portion of IgG (a 63,000/55,000 dimer[33]), for serum complement molecules (a 155,000 to 177,000 molecule with alpha and beta subunits for the C3bi receptor[34-36]), for FMLP (68,000 mol wt[37]), and for PMA.[38] To date, the C3bi receptor has been best studied because of its recognition by the monoclonal antibodies OKM1, Mol, Mac-1, and others.[8,20,36] Congenital absence of the Mol antigen has been associated with defects of C′ mediated binding as well as defects of PMN adherence, chemotaxis, aggregation, phagocytosis, and antibody-dependent cytotoxicity.[39] Because of its cell-activating effects, its inhibition of EAC rosetting, and its recognition of a 94,000-mol wt PMN surface structure, Ab 1-14 may be recognizing an epitope on or near the binding site of the 94,000-mol wt β-subunit of the C3bi complex. Along a similar vein, the monoclonal antibody 60.3 has been shown to recognize a 95,000/130,000/150,000 mol wt complex on neutrophils, lymphocytes, and monocytes, and it may be possible that antibodies 1-14 and 1-15 recognize subcomponents of this complex. When compared with the monoclonals OKM1/Mol and 60.3, however, it is worthy to note the high specificity of antibody 1-14 and antibody 1-15 for neutrophils. Because the C3bi receptor and the 60.3 antigen are known to be common to PMNs, monocytes, and lymphocytes, the apparent PMN specificity of Ab 1-14 and Ab 1-15 argues against their recognition of these molecules. Further, the function-modulating effects of 1-15 and 1-14 were not specific for either FMLP- or PMA-induced cell stimulation, and neither antibody had an effect on PMN superoxide response to opsonized zymosan. These data suggest that the 1-14 and 1-15 antibodies are not binding to specific receptor

Table 4. Summary: Alteration of PMN Function by Monoclonal Antibodies

			Reported Effects on PMN Function in Vitro

molecules, but rather that they bind to molecules involved in the function of several PMN activation pathways. Further studies, including competitive binding and preabsorption experiments with purified antigens, will be required to define the specificity and cross-reactivity of OKM1, 60.3, 1-15, and 1-14. Immunoaffinity antigen purification should allow more precise definition of the 1-14 and 1-15 antigens and their role in the sequence of neutrophil activation.

Monoclonal antibodies have been shown to provide tools for study of the phenotypic expression of neutrophil antigens in developing granulocytes and myeloid tumor cells.[40-42] At present, the availability of nine PMN function-inhibiting monoclonal reagents offers researchers the potential to dissect specific pathways of PMN activation by inflammatory stimuli. Further studies using these reagents will allow isolation of individual PMN membrane molecules and identification of their function in neutrophil recognition of inflammatory stimuli.

ACKNOWLEDGMENT

We thank C.M. Carpenter, Barbara Bishop, and T. Egwang for technical assistance and Pat Amato for help in the preparation of the manuscript.

The Risks of Central Nervous System Relapse and Leukoencephalopathy in Patients Receiving Marrow Transplants for Acute Leukemia

By Craig B. Thompson, Jean E. Sanders, Nancy Flournoy, C. Dean Buckner, and E. Donnall Thomas

The records of 415 patients who received allogeneic marrow transplants for acute leukemia were reviewed to assess the risk of central nervous system (CNS) relapse and leukoencephalopathy after marrow transplantation. The Kaplan-Meier estimates of the probability of CNS relapse posttransplant were 13% for patients with acute lymphoblastic leukemia (ALL) and 2% for patients with acute nonlymphoblastic leukemia (ANL). Previous CNS disease was significantly correlated with an increased risk of CNS relapse in patients transplanted for ALL but not for ANL. In contrast, bone marrow involvement with leukemia at the time of transplant was associated with an increased risk of CNS relapse in patients with ANL but not in patients with ALL. Seventy-one patients with ALL did not receive posttransplant intrathecal methotrexate (IT-MTX) and 127 did. The probability of CNS relapse in these two groups was 38% and 7%, respectively ($P < .02$). This protective benefit from IT-MTX was present in patients both with and without a history of CNS involvement or marrow involvement at the time of transplant. In patients with ANL, 116 patients did not receive posttransplant IT-MTX and 101 patients did, but no protection from CNS relapse was observed from IT-MTX irrespective of a patient's previous CNS history or marrow status at the time of transplant. Leukoencephalopathy was seen exclusively in patients who had received radiation and/or intrathecal chemotherapy to the CNS before preparation for marrow transplantation and posttransplant IT-MTX. In such patients the risk of leukoencephalopathy was 7%. From our data, it appears that posttransplant IT-MTX is a significant benefit for ALL patients in preventing CNS relapse after marrow transplantation. A similar benefit from posttransplant IT-MTX for ANL patients cannot be established from this study. In both groups, increasing total CNS therapy was associated with an increasing risk of leukoencephalopathy.

WE HAVE REPORTED the results for patients with acute leukemia who were transplanted in relapse after cyclophosphamide with or without other chemotherapeutic agents and total body irradiation (TBI).[1] In that study, four of 46 patients with acute lymphoblastic leukemia (ALL) relapsed initially in the central nervous system (CNS). In the 54 patients with acute nonlymphoblastic leukemia (ANL), there was one CNS relapse. It was anticipated that CNS relapses would increase as the fraction of early deaths and of patients dying of nonleukemic causes decreased in patients with ALL and possibly ANL. Based on these early studies, we initiated more intensive posttransplant prophylactic CNS therapy. This report presents an analysis of these attempts to eliminate CNS leukemia after transplant and to evaluate the occurrence of leukoencephalopathy.

MATERIALS AND METHODS

Four hundred fifteen patients with acute leukemia received allogeneic marrow transplants from December 1970 through December 1980 and were analyzed as of June 1984. In all patients, informed consent was obtained prior to transplantation. Protocols and consent forms were approved by the Institutional Review Board of the Fred Hutchinson Cancer Research Center. Patients transplanted at Children's Orthopedic Hospital have been reported elsewhere and are not included in the analysis.[2] Previous chemotherapy and CNS therapy varied with the disease history and the referring institution. All patients received TBI 9.2 to 10.0 Gy in a single exposure[3,4] or fractionated to a total dose of 12.0 to 17.5 Gy.[5,6] TBI was administered from opposing Cobalt 60 sources at a dose rate of 6 to 8 cGy/min. After TBI, 353 of the patients received cyclophosphamide, 120 mg/kg, in two divided doses. The remaining patients received a variety of supplemental chemotherapies as part of their conditioning regimen as described previously.[7] All patients received allogeneic transplants from family member donors who were HLA-compatible as determined by serologic typing and mixed leukocyte culture tests.[1]

The history of CNS leukemia was obtained from patient records. Active CNS disease was defined as the presence of leukemic blasts in the cytocentrifuge preparation or elevated and abnormal cerebrospinal fluid cell counts with clinical CNS symptoms at the time of initiating the marrow transplant preparative regimen.[8] Before 1976, patients received treatment for CNS disease on an individualized basis, and methotrexate (MTX) was administered intravenously (IV) on days 1, 3, 6, and 11 and then on a weekly basis until day 102 to prevent or ameliorate graft-*v*-host disease (GVHD).[1] From 1976 on, all patients were to receive two doses of intrathecal methotrexate (IT-MTX) in the ten days before marrow infusion (day 0). Posttransplant MTX was to be given intrathecally beginning on day 32 and on alternate weeks until day 102; IV-MTX was given on the alternate weeks. Patients with a history of or active CNS disease were to receive an additional eight doses of IT-MTX, given every other month after day 102. The IV-MTX dose was 15 mg/m^2 on day 1 and 10 mg/m^2 thereafter. The IT-MTX dose was 12 mg except in patients under 3 years of age, where 6 mg was used.[9]

After marrow transplantation, CNS relapse was defined either as meningeal leukemia occurring as the first site of recurrent leukemia or as meningeal leukemia occurring simultaneously with marrow recurrence. Patients who developed recurrent leukemia initially in marrow and then developed CNS leukemia were not considered to have had a primary CNS relapse.

Leukoencephalopathy (LEC) was defined as a clinical picture of lethargy, slurred speech, ataxia, seizures, confusion, dysphagia, spasticity, and decerebrate posturing with pathological findings of degeneration of the white matter with multifocal to confluent noninflammatory necrosis.[10]

Tables 1 and 2 show the patient characteristics before transplantation. Patients were considered in remission if they had less than 5% blasts in the marrow. Of patients with ALL in remission, only 17 were in first remission; the rest were in a second or subsequent remission.

All estimates of the probability of CNS relapse and development of LEC were made using the method of Kaplan and Meier.[11] Differences between the patient groups were evaluated using the generalized Savage log rank test for censored observations.[12] Multivariate statistical methods were not used because of the low absolute frequency of CNS relapse and of LEC. Instead, the log rank test was used to rank potential risk factors and combinations of them. Risk factors evaluated included marrow status at the time of transplant, CNS leukemia involvement before or at the time of transplant, patient age, patient sex, acute or chronic GVHD, and TBI preparative regimen.

RESULTS

Central Nervous System Relapse

Acute lymphoblastic leukemia. Eleven of 198 patients transplanted for ALL relapsed in the CNS after marrow transplantation (Table 1). Six patients were in marrow remission and five patients were in marrow relapse at the time of transplant. Marrow status at the time of transplant was not associated with the risk of CNS relapse. Sixty-six of the 198 patients transplanted for ALL had a history of CNS involvement and/or CNS leukemia at the time of transplant, and they were found to have had a higher probability of CNS relapse after transplant than patients without a history of prior CNS involvement ($P < .02$).

Seventy-one of the 198 patients transplanted for ALL did not receive posttransplant IT-MTX. Forty-six did not receive IT-MTX because they were transplanted before the initiation of the posttransplant IT-MTX protocol, and 25 had IT-MTX omitted due to severe metabolic abnormalities, poor marrow graft function, or platelet support problems. Figure 1 shows the effect of posttransplant IT-MTX with respect to the probability of CNS relapse after transplant. There was a statistically significant decrease in the incidence of CNS relapse in patients who received posttransplant IT-MTX ($P < .02$). This improvement was seen independently of whether patients were in marrow remission or relapse at the time of transplant.

Table 1. Characteristics of Patients With Acute Lymphoblastic Leukemia

Bone Marrow Status at Transplant	Remission	Relapse

Time from transplant to CNS relapse, range in months (median)	—	1–5 (5)

When the effects of posttransplant IT-MTX were stratified according to the patient's CNS leukemia status at the time of transplant, it was found that there was a 19% probability of CNS relapse after transplant in patients without a history of CNS disease who did not receive IT-MTX, while only 4% of such patients who received IT-MTX relapsed. Among patients with a history of and/or active CNS disease, there was a 52% probability of CNS relapse in patients who did not receive IT-MTX, while the probability of CNS relapse was 17% among patients who did.

Other factors that failed to show an association with the risk of CNS relapse included acute or chronic GVHD, age, and sex.

Acute nonlymphoblastic leukemia. Three of 217 patients transplanted for ANL relapsed in the CNS (Table

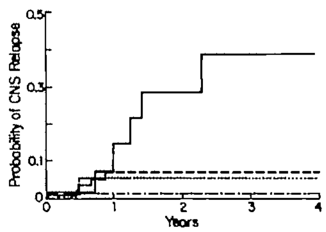

Fig 1. Kaplan-Meier probability of central nervous system relapse after marrow transplantation. Effect of posttransplant intrathecal methotrexate (IT-MTX) on patients with either ALL or ANL. (—) Patients with ALL who did not receive posttransplant IT-MTX (7/71 alive at day 1,460). (– – –) Patients with ALL who received posttransplant IT-MTX (29/127 alive at day 1,460). (· · · ·) Patients with ANL who did not receive IT-MTX (7/101 alive at day 1,460). (—·—·) Patients with ANL who received IT-MTX (45/116 alive at day 1,460). Patients with ALL who received IT-MTX had a significantly lower probability of CNS relapse than did patients with ALL who did not receive IT-MTX ($P < .02$). Differences in the probability of CNS relapse in patients with ANL grouped by posttransplant IT-MTX status were not statistically significant.

2). All three patients were in marrow relapse at the time of transplantation, and transplantation in marrow relapse was significantly associated with an increased risk of posttransplant CNS relapse ($P < .02$). Thirty-one of the 217 patients transplanted for ANL had a history of CNS involvement and/or CNS leukemia at the time of transplant. The influence of previous CNS disease was evaluated with respect to CNS relapse after transplant and no effect was detectable. There was a probability of 3% that patients with CNS disease before transplant would relapse in the CNS after transplant and a probability of 2% that patients who had not had previous CNS disease would relapse in the CNS.

Twenty-five patients transplanted in remission and 76 transplanted in relapse did not receive posttransplant IT-MTX. Two of the remission patients and 52 of the relapse patients were transplanted before the initiation of the IT-MTX protocol. Posttransplant IT-MTX was omitted in 47 patients due to severe platelet support problems, metabolic abnormalities, and/or poor marrow graft function. IT-MTX posttransplant did not significantly reduce the probability of CNS relapse (Fig 1). The slightly lower probability of CNS relapse in the group who received IT-MTX was entirely accounted for by the lower proportion of patients transplanted in marrow relapse in that group. Analysis of posttransplant IT-MTX in patients grouped by previous CNS disease status also failed to show any significant effect from receiving IT-MTX with respect to CNS relapse. Other factors with no detectable effect on the risk of CNS relapse included acute or chronic GVHD, age, and sex.

Leukoencephalopathy. Seven of the 415 patients developed LEC after marrow transplantation (Table 3). Due to the small numbers of patients who developed LEC, and because CNS toxicity should be independent of the type of leukemia, patients with ALL and ANL were evaluated together. There was no statistically significant relationship between a history of CNS disease and the development of LEC. All seven cases of LEC were found to have occurred among the 201 patients who had received either prophylactic or therapeutic treatment (radiation and/or IT therapy) of the CNS before marrow transplant. None of the 214 patients transplanted without a history of prior CNS treatment developed LEC ($P < .01$). All seven patients who developed LEC were in the group of 243 patients who received posttransplant IT-MTX ($P < .05$). Five of these seven patients were among the 57 patients who received six or more doses of IT-MTX posttransplant, one patient was among the 83 who received four to five IT-MTX doses, and one was among the 103 receiving one to three doses.

No patient who received posttransplant IT-MTX without previous CNS therapy developed LEC. Similarly, no patient who received previous CNS therapy without posttransplant IT-MTX developed LEC. Therefore, the risk of LEC was further evaluated only among patients who had previous CNS therapy and received posttransplant IT-MTX (Table 4). The overall risk of LEC in this group was 7%. Within this group, there was an increasing risk of LEC associated with an increasing number of doses of IT-MTX ($P < .01$).

Among the factors with no detectable effect on LEC were age, sex, acute or chronic GVHD, and bone marrow status at the time of transplant.

DISCUSSION

CNS prophylaxis has become routine for patients with ALL[13–15] but has been controversial in patients with

ANL.[16-18] The purpose of this retrospective analysis is to define the risks of CNS relapse and the complications of CNS prophylactic therapy occurring after marrow transplantation. The data presented here were derived from two distinct time periods of marrow transplantation in Seattle. Among the first 100 patients, there were five relapses in the CNS, and the actuarial probability of CNS relapse for these patients was 21%.[19] In an effort to decrease this relapse probability, posttransplant IT prophylaxis with methotrexate was initiated. Six doses of posttransplant IT-MTX were selected for patients without a history of and/or active CNS leukemia at transplant, based on the assumption that a one $\log_{10}$ cell kill would result per dose of IT-MTX[20] and that the estimated number of blasts in occult leukemia is less than 10^6.[21]

The data presented here show that prophylactic CNS therapy posttransplant reduced the risk of CNS relapse for patients without a history of CNS leukemia who were transplanted for ALL. In patients without a history of CNS leukemia transplanted for ANL, no benefit of posttransplant IT-MTX could be demonstrated. However, the probability of CNS relapse for ANL patients given marrow grafts (2%) was lower than would be expected from the reported experience with patients treated with chemotherapy.[18] In fact, none of the 115 patients transplanted for ANL in remission relapsed in the CNS, and 39 of these patients are long-term survivors. This suggests that either our patient group is biased toward a population of patients at low risk for CNS relapse or, more likely, that the basic marrow conditioning regimen provides adequate CNS prophylaxis to this group.

Once CNS leukemia has occurred, the probability of achieving long-term continued complete remission is poor with conventional therapy.[22,23] Treatment of CNS leukemia is difficult because the number of intrathecal chemotherapeutic agents is small and drug resistance may develop rapidly. The irradiation therapy that the brain can safely receive is also limited.[24] Sixty-eight of 197 (35%) patients with ALL came to transplant with a history of and/or active CNS disease, and 31 of 218 (14%) patients with ANL came with CNS disease history or active CNS disease. The presence of CNS disease at any time was shown to be a significant risk factor for CNS relapse after marrow transplantation for patients with ALL ($P < .02$) but not for patients with ANL. However, patients with ALL and a history of CNS leukemia who received IT-MTX posttransplant experienced a threefold decrease in their incidence of CNS relapse, from 52% to 17%. In contrast, ANL patients with a previous history of CNS leukemia did not appear to benefit significantly from posttransplant IT-MTX with respect to CNS relapse.

As with most therapies, posttransplant IT-MTX was not without toxicity. Both irradiation and intrathecal chemotherapy have been associated with neurotoxicity, the most devastating of which is progressive LEC.[25-29] From our results, it appears that the risk of LEC after marrow transplantation is apparently not limited to children. Three of the seven patients in our study who developed LEC were over age 20 at the time of transplant, and age was not found to be a risk factor for the development of LEC in our analysis. In addition, LEC occurred only in patients who received pretransplant CNS therapy (CNS irradiation and/or IT chemotherapy) before the transplant. This suggests that neither the basic marrow conditioning regimen (consisting of cyclophosphamide, TBI, and IT-MTX) nor the addition of a course of posttransplant IT-MTX, is sufficient to cause a significant risk of LEC. However, most patients with ALL now routinely receive CNS prophylaxis.[15] Johnson et al[2] have reported that four of 24 marrow transplant recipients who had received CNS prophylaxis and who received six or more doses of IT-MTX posttransplant developed LEC (17%). In our study, we found that five of the seven patients who developed LEC were among 36 patients who received both CNS therapy before transplant and six doses of IT-MTX posttransplant (14%). Of the remaining two patients, one developed LEC after four doses of 12 mg MTX by way of Ommaya reservoir. Cerebrospinal fluid (CSF) MTX levels were measured and found to be markedly elevated. None of the other six patients who developed LEC had CSF MTX levels measured, and all received MTX by way of lumbar punctures. Lower doses of MTX administered by way of Ommaya reservoir may avoid neurotoxicity.[30,31] The remaining patient who developed LEC had received two full courses of IT therapy before marrow transplant and developed LEC after receiving only one dose of IT-MTX posttransplant.

As posttransplant IT-MTX appears to be beneficial in preventing CNS relapse in patients with ALL, we did attempt an analysis to determine the optimum number of IT-MTX doses after transplantation that would prevent CNS relapse. The data suggested that there was no added benefit from more than four to five doses of posttransplant IT-MTX irrespective of CNS leukemia status at transplantation. At these dosage levels, there is less than a 2% risk of developing LEC. More doses of IT-MTX were associated with an increased risk of LEC without any further protection from CNS relapse. It must be remembered, however, that these data were determined retrospectively, and that no uniform CNS treatment protocol was followed in our patients before transplantation. The optimum number of posttransplant IT-MTX doses is likely to vary from patient to patient and center to center, depending on the extent of previous CNS therapy and the perceived risk of CNS therapy.

Disparities in Estimates of IgG Bound to Normal Platelets

By Neil Blumberg, Debra Masel, and Mark Stoler

Estimates of the number of IgG molecules bound to normal platelets have ranged from several hundred to several tens of thousands. The lower estimates were generated from direct binding assays and stoichiometric assumptions. The higher values derive from competitive binding assays, in which platelet-associated IgG (PAIgG) is calculated from a standard curve using soluble IgG standards. Using a kinetic-ELISA (enzyme-linked immunosorbent assay) antiglobulin assay, we measured normal platelet IgG to be 21,200 ± 9,400 molecules per platelet when a competitive assay and soluble IgG standards were used. Direct measurement of bound antiglobulin by kinetic-ELISA and stoichiometric assumptions yielded a measurement of 259 ± 117 IgG molecules per platelet. Soluble IgG and PAIgG are not comparable in their ability to bind anti-IgG. Disparities in estimates of normal PAIgG are probably due to methodological differences. The estimate most likely to be correct is several hundred IgG or less per normal platelet.

© 1986 by Grune & Stratton, Inc.

ESTIMATES OF NORMAL LEVELS of platelet-associated IgG (PAIgG) have generally ranged from 1 to 10 fg per platelet.[1,2] This corresponds to 4,000 to 40,000 molecules of IgG per platelet, or 10^2- to 10^3-fold greater than estimates for normal red cell-associated IgG.[3] Two reports have estimated normal PAIgG levels at 169 and 235 molecules of IgG per normal platelet, respectively.[4,5] LoBuglio et al[4] suggested their lower results might be due to their use of a monoclonal anti-IgG reagent and to elimination of platelet fragments from their assay.

In general, all studies with higher estimates of PAIgG used competitive assays. In these, platelet binding of anti-IgG is compared with the binding of standard concentrations of soluble IgG to anti-IgG. The two lower estimates were derived from calculations of the theoretical maximum number of anti-IgG molecules present in the antiglobulin reagent, followed by direct measurement of the proportion of anti-IgG binding to normal platelets.[4,5] The high levels of PAIgG reported in most studies have raised questions as to the specificity of the assays used to measure PAIgG.[6-8]

Ware et al[9,10] have reported that use of an assay calibrated with soluble IgG as standards gave greatly increased estimates of PAIgG compared with the estimates derived from a direct monoclonal anti-IgG binding assay and stoichiometric calculations. They reported that using a direct binding assay, monoclonal anti-IgG studies yielded a result of 500 to 1,000 IgG molecules per normal platelet.[10] Using polyclonal anti-IgG, the result was 2,000 to 3,000 IgG per cell.[10] To confirm these findings and evaluate methodological variations as a cause for disparities in estimates of normal levels of PAIgG, we measured PAIgG by two methods, using the same polyclonal antiglobulin reagent in each. One method was a competitive binding assay using calibration by soluble IgG standards. The other method used measurement of anti-IgG binding to normal platelets and stoichiometric derivation of the number of anti-IgG molecules bound.

MATERIALS AND METHODS

Competitive assay for PAIgG using calibration with a soluble IgG standard curve. In this assay, PAIgG or soluble IgG standards compete with solid-phase IgG for binding to an alkaline phosphatase-linked anti-IgG antiglobulin reagent. The principle of the assay is that increased concentrations of soluble IgG or PAIgG will compete for anti-IgG and reduce anti-IgG binding to the solid-phase IgG. The solid-phase is a 96-well microtiter plate (Immulon II, Dynatech, Inc, Alexandria, Va) that has been previously washed three times with distilled water. All washes are performed by machine (Miniwash, Dynatech). A 100-μL solution of 100 ng purified human IgG (Pelfreeze Biologicals, Rogers, Ark) in coating buffer (1.59 g/L Na_2CO_3, 2.93 g/L $NaHCO_3$, pH 9.8) is placed in each well and incubated overnight at 4 °C. Two wells are coated and incubated with 100 ng of purified bovine serum albumin (BSA) (Sigma Chemical Co, St Louis) in coating buffer as negative controls. No binding of anti-IgG–alkaline phosphatase conjugate should occur in these two wells.

Platelets are prepared from EDTA anticoagulated normal donor blood collected in evacuated collection tubes (Sherwood, St Louis). Platelet-rich plasma is made by centrifugation at 250 g for ten minutes, and three washes are performed with phosphate-buffered saline (PBS)-EDTA (3.0 g/L Na_2 EDTA, 3.75 g/L Na_2HPO_4, 8.2 g/L NaCl, pH 7.0). Platelets are resuspended at a count of 50,000/μL in PBS-Tween (PBS as earlier, without EDTA, but with 0.5 ml/L Tween 20 [Sigma, St Louis]). Removal of possible platelet fragments was not attempted.

A series of dilutions of purified IgG is prepared containing 25, 50, 100, 250, 500, 750, and 1,000 ng in 100 μL of PBS-Tween. These serve as soluble standards to compete with the solid-phase IgG for alkaline phosphatase–anti-IgG conjugate.

The microtiter plate coated with IgG is washed four times with PBS-Tween before use. The soluble IgG standard curve dilutions are added to individual wells in triplicate, as are 100 μL of 50,000/μL solutions of washed platelets (total 5 × 10^6 per well). Several duplicate wells are used as negative controls. The BSA-coated wells receive 100 μL of PBS-Tween. Two IgG-coated wells receive 100 μL of PBS-Tween to serve as zero points for competitive binding (ie, maximal binding of anti-IgG due to lack of competing soluble IgG). Two wells coated with IgG receive neither soluble IgG, platelets, nor anti-IgG, to serve as controls for spontaneous substrate conversion. PBS-Tween (200 μL) is added instead. Once all soluble IgG standards and the platelets have been added, 100 μL of a 1:300 dilution (in PBS-1% BSA) of alkaline phosphatase coupled to affinity-purified antihuman IgG (Sigma) is added to each well, except as noted earlier. The plate is then gently rotated (Microshaker, Dynatech) for one minute, covered with a plastic seal, and incubated at 37 °C for one hour. The contents are then dispelled by inversion, and the plate washed four times with PBS-Tween. Substrate is added to each well (200 μL of 1 mg/mL *p*-nitrophenylphosphate (Sigma) in 5.3 g/L Na_2CO_3, 0.2 g/L $MgCl_2 \cdot 6H_2O$, pH 9.8).

The plate is rotated for 18 minutes, and determination of bound anti-IgG conjugate is performed automatically by a through-the-plate spectrophotometer (Dynatech MR600) coupled to an Apple IIe computer (software program available from Dr Jonathan Cowles, 149 Tobey Rd, Pittsford, NY 14534). Bound anti-IgG conjugate is determined kinetically as ΔA_{405nm}/min × 1,000. Bound anti-IgG has been shown to be linearly proportional to this slope in a kinetic-ELISA (enzyme-linked immunosorbent assay).[11] A standard curve of slope (ΔA_{405nm}/min × 1,000) *v* ng IgG in the soluble standards is constructed to calibrate the assay. This is linear over the range of the assay when a log-linear plot is used (see Fig 1). The quantity of IgG bound to 5×10^6 platelets is calculated by using the measured mean ΔA_{405nm}/min × 1,000 and the standard curve. Values are reported as 10^{-15} g (fg) IgG per platelet. These are converted to molecules of IgG per platelet assuming a molecular weight (mol wt) of 150,000 daltons.

Direct binding assay for PAIgG. The alternative method for measuring PAIgG involves stoichiometric calculation of the activity of the alkaline phosphatase–anti-IgG conjugate (number of anti-IgG molecules added per test) and measurement of the proportion of the conjugate that actually binds to 5×10^6 platelets. The calculations of the number of anti-IgG added are shown in the next section.

The measurement of percentage binding to 5×10^6 platelets is performed as follows: The microtiter plate is not coated with IgG, since it serves only as a reaction vessel. Washed platelets (5×10^6) (100 μL) are incubated with 100 μL of a 1:300 dilution of the same alkaline phosphatase–anti-IgG conjugate used in the competitive assay. The incubation conditions are identical: 37 °C for one hour. The platelets are sedimented at 500 g for ten minutes and washed at 500 g for five minutes four times with PBS-Tween. Loss of platelets under these conditions is usually <10%. Substrate is added and ΔA_{405nm}/min × 1,000 is determined exactly as in the competitive assay. Here we measure anti-IgG conjugate bound to platelets rather than to the solid-phase IgG on the plate. The amount of alkaline phosphatase–anti-IgG added is quantitated by measuring the ΔA_{405nm}/min × 1,000 of the unreacted original anti-IgG conjugate, before its incubation with platelets. Thus, a ratio of ΔA_{405nm}/min × 1,000, platelets per original anti-IgG conjugate is a measure of the proportion of the added anti-IgG conjugate that has been bound to the platelets. By calculating (activity bound to platelets) × (number of anti-IgG conjugate molecules added) we arrive at an estimate of the maximum number of anti-IgG molecules present on the platelets.

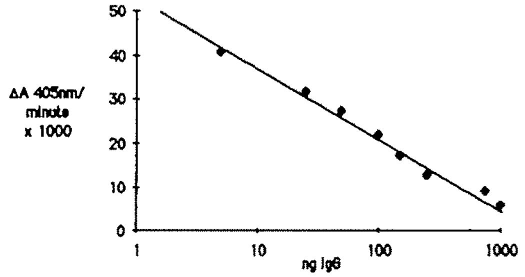

Fig 1. Typical scatter diagram for the competitive kinetic-ELISA. Standard dilutions of purified IgG are plotted on the logarithmic axis *v* the mean ΔA_{405nm}/min × 1,000 measured on the linear axis. Increasing amounts of soluble IgG reduce the binding of anti-IgG–alkaline phosphatase conjugate to the solid-phase IgG. A linear standard curve is constructed by least squares linear regression of ΔA_{405nm}/min × 1,000 *v* the log of the IgG concentration. The *r* value for this line usually is 0.99 or better. The nanograms of IgG per 5×10^6 platelets in the assay is derived by interpolation on this standard curve using the mean measured ΔA_{405nm}/min × 1,000 for the platelet suspension.

Calculation of the maximum number of anti-IgG molecules present in the alkaline phosphatase–anti-IgG conjugate. A number of assumptions must be made to allow these calculations: (1) enzyme and anti-IgG biological activity are unchanged by the conjugation process; (2) the ratio of anti-IgG to enzyme in the conjugate is 1:1; and (3) each anti-IgG–enzyme conjugate binds to one IgG on the platelet surface. The overall effect of these assumptions is likely to be overestimation of the number of binding sites on the platelet, since (1) the method used for conjugation probably leads to <1% of the conjugate being fully immunologically and enzymatically reactive[12]; (2) the ratio of anti-IgG to enzyme in the conjugate is probably much less than one, since threefold more enzyme than anti-IgG by weight is reacted in the conjugation process[13]; and (3) the third assumption, if incorrect, could underestimate PAIgG by twofold, if all anti-IgG–enzyme conjugate molecules were bound to two IgG molecules each, the theoretical maximum.

The calculations are as follows:

1. Conjugate enzyme activity, as measured by the manufacturer: 208 U/mL. Units added per well: (208 U/mL) (0.1 mL) (1/300 dilution) = 6.93×10^{-2} units.
2. Specific activity of the alkaline phosphatase before conjugation: 1,000 U/mg = 0.001 mg/U.
3. Mass of enzyme added per well = (6.93×10^{-2} units) (0.001 mg/U) = 6.93×10^{-5} mg.
4. Mol wt of alkaline phosphatase ≈100,000.
5. Moles of enzyme added per well = (6.93×10^{-5} mg) (10^{-8} mol/mg) = 6.93×10^{-13} mol.
6. Assume 1:1 conjugation of enzyme to anti-IgG. Thus moles of enzyme = moles of anti-IgG.
7. (6.93×10^{-13} mol anti-IgG) (6.02×10^{23} molecules per mole) = 4.17×10^{11} molecules of anti-IgG per reaction.
8. Maximum number of anti-IgG reacted per platelet is thus, theoretically:

$$\frac{4.17 \times 10^{11}\ \text{anti-IgG}}{5 \times 10^{6}\ \text{platelets}} = 83{,}400 \text{ molecules of anti-IgG per platelet.}$$

RESULTS

The mean normal PAIgG using the competitive assay, calibrated by standard curves of soluble IgG to convert ΔA_{405nm}/min × 1,000 to mass units, was 5.3 ± 2.36 fg per platelet (n = 324) (±1 SD). Using a mol wt of 150,000 daltons for IgG, this converts to approximately 21,300 IgG molecules per platelet. PAIgG of patients with immune thrombocytopenia are usually fivefold to 100-fold higher than these levels (Fig 2). Patients with acute leukemia and sepsis also have elevated levels of PAIgG in many instances.

The proportion of conjugate binding to normal platelets in the direct assay, as quantitated by the ratio ΔA_{405nm} platelets/ΔA_{405nm} unreacted conjugate, was 0.31% ± 0.14% (n = 5). That this low-level binding is not due to inadequate amounts of anti-IgG in the 1:300 dilution of antiglobulin conjugate is evidenced by the fact that binding increases many fold when platelets heavily coated with IgG are used in the assay as described. Conversion to number of IgG molecules per platelet is by multiplying the mean percentage binding (0.31%) by the maximum theoretical number of anti-IgG molecules reacted per platelet (83,400) = 259 molecules per platelet.

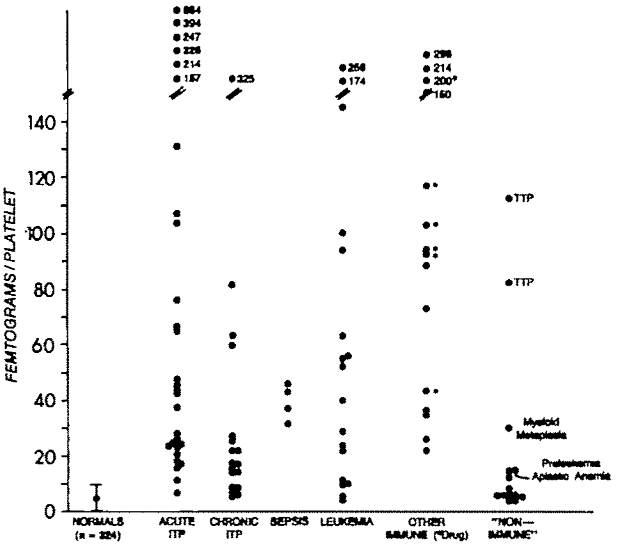

Fig 2. Pattern of elevated PAIgG in selected patients with various types of thrombocytopenia. ITP, idiopathic thrombocytopenic purpura; TTP, thrombotic thrombocytopenic purpura. Further details on these patients are available from the authors. Determinations by competitive assay employing soluble IgG standards.

DISCUSSION

Our results confirm the findings of Rosse et al[9,10] that disparities between high and low estimates of normal PAIgG levels are the result of differences in methodology and calculation technique. We believe that the estimates based on stoichiometric calculations and direct measurement of anti-IgG binding, such as those used by Lepoirrier's,[5] LoBuglio's,[4] and Rosse's[9,10] groups, are likely to represent truer estimates of PAIgG. They rest on scientifically reasonable assumptions and are not likely to be incorrect by more than a factor of two. As discussed in Materials and Methods, the assumptions used are, in fact, more likely to overestimate PAIgG. Although most PAIgG assays use a two-stage antiglobulin procedure,[1] we used a typical competitive one-stage immunoassay.[14] There are no theoretical or practical reasons why this should have affected our results.

Methods for PAIgG determinations calibrated using soluble IgG rest on the assumption that PAIgG and soluble IgG standards compete equally well for anti-IgG. Ware et al's[9,10] data argue strongly against the accuracy of this assumption. One possible explanation for this disparity is that the location on the platelet of PAIgG might favor bivalent binding kinetics for an anti-IgG reagent, rather than the univalent binding kinetics that apply to solution reactions between anti-IgG and IgG. The difference between univalent and bivalent affinity constants can be as much as tenfold to 100-fold.[15] This possibility could be studied by using anti-IgG reagents with univalent binding properties [eg, F(ab) fragments].

In summary, use of a standard curve of soluble IgG to measure levels of PAIgG overestimate the actual number of molecules per platelet by approximately 80-fold in our hands. Results of PAIgG estimates using soluble IgG standards should perhaps be reported as "fg per platelet in soluble IgG equivalents." We believe that our data and those in the literature are most consistent with a maximal estimate of <300 molecules of IgG per normal platelet.

ACKNOWLEDGMENT

We thank Drs Joanna Heal and Dean Arvan for helpful discussions. Carol Cole provided exemplary secretarial assistance. Kathy Lopez, Debby Polidori-Schwartz, Gail Smyth, and Glenda Spencer assisted in the normal range study.

Human Thrombocytopenia Is Associated With Structural Abnormalities of the Endothelium That Are Ameliorated by Glucocorticosteriod Administration

By Craig S. Kitchens and J.F. Pendergast

Capillary fragility is characteristic of severe thrombocytopenia. This mechanical weakness may not be solely accounted for by decreased ability of platelets to repair endothelial breaks. Platelets may have a role in maintaining endothelial hemeostasis. This laboratory has demonstrated thinnning of capillary endothelium in experimental thrombocytopenia. We now report similar findings in human thrombocytopenia. Capillary endothelium supplying either skin or skeletal muscle was found to have a mean thickness only half that of normal as well as frequent very thinned areas, including some fenestrations. All findings reverted toward normal after four days of prednisone administration at a time the degree of thrombocytopenia was equally severe. These findings are consistent with the hypothesis that platelets are necessary for normal structure and function of endothelial cells and that glucocorticosteroid administration may ameliorate the pathophysiology of thrombocytopenia.

© *1986 by Grune & Stratton, Inc.*

ADEQUATE NUMBERS of functional platelets are necessary for normal hemostasis. Platelets seal endothelial breaks in the event of rupture. Claiming that lack of this sealing function alone does not account for capillary fragility seen in severe thrombocytopenia, it has been hypothesized that platelets additionally, in some manner, may play a role in maintaining endothelial integrity.[1,2] This laboratory has published morphological data in experimental thrombocytopenia in rabbits supporting this hypothesis.[3] We have additionally demonstrated that endothelial structural alterations in this experimental model were ameliorated by the administration of glucocorticosterioids.[4] Herein are reported observations made on tissue obtained from humans with severe thrombocytopenia.

MATERIALS AND METHODS

Patients. Strict criteria for patient accession accounts for the few patients accrued over a five-year period. Patients had to have severe thrombocytopenia ($\leq 15{,}000/\mu L$) not due to a process (chemotherapy or radiation therapy) that conceivably could directly damage a variety of tissues, including endothelium. The platelet count had to remain $\leq 15{,}000/\mu L$ after four days of daily administration of prednisone, 1 mg/kg, in order to minimize endothelial structural changes related primarily to resolution of thrombocytopenia. Before their entry into the study, they could not have received glucocorticosteroids. Because of our strong feelings that glucocorticosteroids are effective for hemorrhage associated with severe thrombocytopenia, we could not ethically accept transfer of thrombocytopenic patients from other cities without first recommending the administration of such agents. This greatly restricted the number of patients who were available to serve in this study comparing determinations made before and during prednisone administration. Finally, patients had to agree to serve in the experiment, all parts of which were approved by the Internal Review Board of the University of Florida.

Tissue. As rapidly as possible after initial evaluation and understanding of the protocol, biopsies were performed after which prednisone, 1 mg/kg/d, was begun. Biopsy material was also obtained on the fourth day of such treatment if the platelet count was still $\leq 15{,}000/\mu L$. If the platelet count was $\geq 15{,}000/\mu L$, the original biopsy material was not further processed. Biopsy material was obtained from skin and muscle. Skin biopsies were taken from the leg in areas near fresh petechiae but not of petechiae themselves. This area was chosen to ensure that capillary fragility was present. Our previous animal studies demonstrated that capillary thinning was not confined to actively hemorrhaging areas, being just as pronounced in normal-appearing tissue.[3,4] An elliptical incision 6 × 2 mm was made with a surgical scalpel deep enough to reach subcutaneous tissue. The wound was closed with three sutures, and pressure dressings were applied. Tissue from the gluteal muscle was obtained using a Lee soft-tissue biopsy needle (Becton Dickinson, Atlanta), which was placed roughly along the axis of the indicated bone marrow aspirate and biopsy tract. Biopsy yielded muscle in both pretreatment and posttreatment attempts in only three patients; therefore, muscle data are complete for only three patients. Data regarding skin biopsy is complete for all five patients. Tissues were then immediately diced in cold 3% glutaraldehyde in phosphate buffer and postfixed in OsO_4. It was then embedded, sectioned, and stained with lead citrate and uranyl acetate as previously described.[3]

Electron microscopy. All material was examined using a Philips 300 electron microscope (Eindhoven, The Netherlands). All photomicrographs were made at a fixed magnification (50,000) without knowledge of patient or status of prednisone administration. It was impossible to be unaware of whether the biopsy source was skin or muscle. Several blocks from each patient sample were examined until approximately 100 capillaries from each biopsy sample had been photographed. All vessels encountered were photographed, regardless of photogenicity, in order to minimize bias in choosing which vessels to photograph.

Collection of data. Before breaking the patient and preparation code, each photomicrograph was examined for (1) "thin spots," (2) fenestrations, and (3) mean thickness of the capillary endothelium. Figure 1 demonstrates these terms. A thin spot is defined as an area in which the endothelium attenuates to a thickness of only 700 to 800 A, the thickness of an endothelial vesicle. This degree of thickness is admittedly arbitrarily selected but being markedly thinner than normal endothelium (4,000 to 6,000 Å), such areas were readily identifiable. Fenestrations are not found in normal endothelium of capillaries supplying muscle or skin (except capillaries supplying sweat glands).[5] Mean capillary thickness was determined using planometric methods previously described.[4] In our experience, this method has a variability of ±2.7%. Because tissue from these patients before they developed thrombocytopenia was not available,

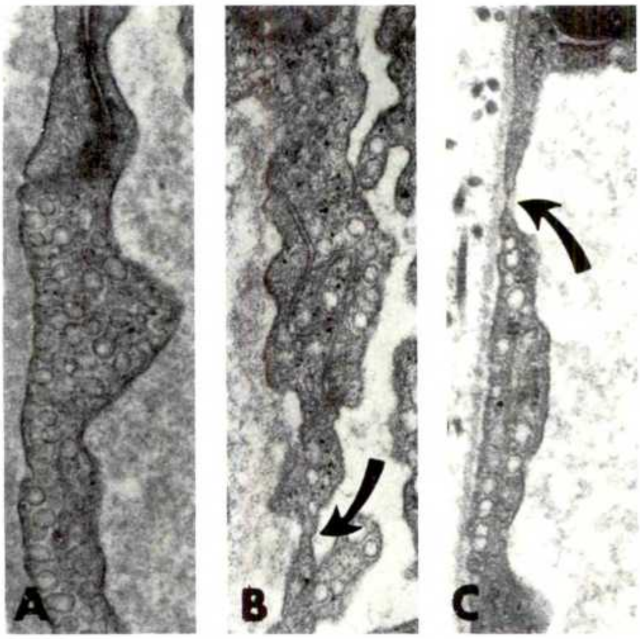

Fig 1. Definition of morphological terms. (A) demonstrates normal endothelium with a thickness of 3,000 to 5,000 Å. (B) shows attenuation to a point of 700 A and is referred to as a "thin spot" (arrow). A fenestration is shown in (C). All figures oriented with capillary lumen to the right and all ×33,000.

determinations from other studies this laboratory has performed using human skin and muscle capillaries were used to define normal.[6,7] The methods were identical. To our knowledge, glucocorticosteroid administration does not affect normal mammalian capillary endothelial structure.[4,6-8] The data were analyzed using the Statistical Analysis System (SAS)[9] computer software package on an IBM 4341 machine in the Faculty Support Center at the University of Florida. Significance of changes in capillary thickness measures was determined using a one-sided paired t test on measures weighted to adjust for the variability within subjects. Comparisons between the study group and normal tissue were made using a two-sample t test, again after weighting the measures to adjust for within-subject variability.[10]

RESULTS

Five patients fulfilled all criteria and their results form the basis of this study (Table 1). Three were diagnosed as having immune thrombocytopenia purpura (ITP) resistant to prednisone administration. Two were initially diagnosed as having amegakaryocytic thrombocytopenia[11,12]; one subsequently developed aplastic anemia, whereas the other's disease evolved into acute nonlymphocytic leukemia.

The response of each patient to prednisone administration was noteworthy. Whereas each patient manifested fresh petechial formation and epistaxis on admission, such hemorrhagic phenomena resolved with the commencement of glucocorticosteroid administration, although the patient's thrombocytopenia did not substantially improve. Likewise, the initial biopsy sites bled significantly, whereas those made on the fourth day bled only little more than similar biopsies performed on patients having normal platelet counts.[13] These events correlated with their template bleeding times, all of which were >20 minutes before prednisone administration and all of which were <20 minutes (mean, 16.5 ± 2.2 minutes; normal, <9.0 minutes) during prednisone administration.

Table 1. Patient Characteristics

			Platelet Count/$10^3/\mu L$	
Age	Sex	Diagnosis	Base Line	1 mg/kg/d Prednisone × Four d
58	F	AMT	4	4
73	M	AMT	3	3
18	F	ITP	2	10
88	M	ITP	2	6
71	M	ITP	11	15

AMT, amegakaryocytic thrombocytopenia; ITP, immune thrombocytopenic purpura.

Table 2 gives our morphological data. Data from the five patients (five pairs of skin biopsies and three pairs of muscle biopsies) were pooled for statistical analysis. Despite the small number of subjects, the capillary endothelium of both skin and muscle is thinner ($P = .001$ and $P = .013$, respectively) and shows more thin spots and fenestrations than normal human endothelium. Additionally, these changes tend to revert toward normal after the administration of glucocorticosteroids ($P = .001$ for skin and $P = .055$ for muscle) at a time when the patients' bleeding was clinically markedly abating. Skin and muscle capillary endothelium in thrombocytopenia after prednisone administration is still thinner than normal endothelium ($P = .001$ for skin and $P = .008$ for muscle). All interendothelial junctions observed were normal.

Data from each individual were also analyzed. Mean capillary thickness was thinner ($P < .05$) in all three muscle and five skin biopsies during thrombocytopenia compared with normal. Mean capillary thickness increased significantly ($P < .05$) after glucocorticosteroid administration in two of the three muscle samples and in all five of the skin specimens. There was no difference in the data whether the thrombocytopenia was due to decreased production (amegakaryocytic thrombocytopenia) or increased destruction (immune thrombocytopenia).

DISCUSSION

The results of this study are remarkably similar to those obtained in our studies of experimental thrombocytopenia

Table 2. Observation of Human Microvascular Endothelium

Material	Thickness + SD	Thin Spots*	Fenestrations*
Skin: normal (n = 36)	5,881 ± 2,399 Å	0.0	0.0
Skin: thrombocytopenia (n = 120)	2,832 ± 933 Å	43.3	6.7
Skin: thrombocytopenia and prednisone (n = 100)	4,040 ± 1,702 Å	5.0	1.0
Muscle: normal (n = 100)	4,180 ± 1,321 Å	0.0	0.0
Muscle: thrombocytopenia (n = 109)	2,074 ± 737 Å	44.9	5.5
Muscle: thrombocytopenia and prednisone (n = 147)	2,552 ± 1,013 Å	20.4	1.3

*Per 100 capillaries.

produced in the rabbit.[4] In each situation, the endothelium during thrombocytopenia becomes roughly half the original thickness, and thin spots and fenestrations are encountered in 43% and 6%, respectively, of the capillaries encountered. After prednisone administration, the endothelial thickness reverts toward normal, assuming approximately 75% of original thickness, while thin spots and fenestrations largely, but not totally, disappeared. Using scanning electron microscopy, we demonstrated enfacement of the capillary endothelial surface in experimental thrombocytopenia. These changes also were partially reversed by prednisone administration.[14] Endothelial alterations similar to those found in humans were also found in dogs rendered severely thrombocytopenic by infusion of thrombin.[8]

As these results during thrombocytopenia are consistent with decreased mechanical strength of the capillary endothelium[7] at a time when capillary fragility and hemorrhage are manifest, it is attractive to hypothesize a casual relationship. As both structural alterations and bleeding are ameliorated by glucocorticosteroid administration, this hypothesis is further strengthened.

The mechanism by which either platelets or glucocorticosteroids may support normal endothelial structure, and hence strength, is not known at this time, but several possibilities exist. Endothelium could appear thinner if fewer endothelial cells were available to cover a fixed luminal surface area. It is unlikely that the number of endothelial cells changes as rapidly as necessary to explain the changes observed in either this clinical study or the previous experimental studies.

Endothelium could appear thinner if the mean circumference of the microcirculation increased. We do not observe any differences among groups of patients (or animals in experimental work) with respect to diameter of capillaries or to how many capillaries were "open" or "closed" as determined by relaxation or constriction of arterioles proximal to the microcirculation. Thinned or fenestrated endothelium was just as likely to be found in a small, flat (ie, "closed") capillary as in a nearly perfectly round capillary. As capillaries themselves lack smooth-muscle cell investiture, their "openness" is determined by proximal blood flow. The law of LaPlace determines that the thin-walled capillary, because of its overall small diameter compared with the rest of the vascular tree, is most resistant to passive engorgement or overinflation due to proximal pressure.

Most likely these alterations are caused by the metabolic effects that platelets and glucocorticosteroids have on endothelial cells. These effects are imperfectly understood and are now being discovered. Platelets can provide prostaglandin endoperoxides to endothelial cells for metabolism.[15,16] King and Buchwald[17] have demonstrated a factor in platelets that promotes endothelial cell growth and is distinct from platelet-derived growth factor. Blajchman et al[18] have demonstrated that hydrocortisone administration decreases vessel wall prostacylin production in vivo. Profound alterations in protein synthesis by endothelial cells studies in vitro are induced by glucocorticosteroids.[19] Any or all of these observations may in part play a role in endothelial cell homeostasis.

Shepro et al[20] were unable to find similar capillary ultrastructural changes in nonquantified observations in experimental thrombocytopenia. The wide variation in endothelial thickness observed in the present study indicates that many vessels in thrombocytopenic preparations may appear normal and many capillaries in normal rabbits or humans may appear thinner than the mean. Only by observing and quantifying many vessels in a blinded morphometric analysis will such changes be statistically apparent.

Platelet Glycoproteins IIb and IIIa Associated With Blood Monocytes Are Derived From Platelets*

By Richard B. Levene and Enrique M. Rabellino

Platelet glycoprotein IIb/IIIa (GP IIb/IIIa), the receptor complex for fibrinogen, has been regarded as a megakaryocyte/platelet lineage-restricted antigen. Recently, however, it has been reported that GP IIb/IIIa is expressed in blood monocytes. Studies were performed to establish the origin and immunological characteristics of monocyte-associated glycoproteins IIb and IIIa (GPs IIb and IIIa). Preparations of blood monocytes containing varying platelet-monocyte ratios were metabolically labeled with [^{35}S]methionine with the expectation that any newly synthesized GPs IIb and IIIa would be monocyte-derived, since platelets have only rudimentary protein synthetic apparatuses. Analyses of sodium dodecyl sulfate (SDS) gels of homogenates of cell preparations containing from 200 to 5:1 platelet-monocyte ratios revealed that unlabeled GPs IIb and IIIa were readily immunoisolated using protein A-Sepharose immunobeads. However, fluorographic analyses of the same cell preparations pulse-labeled with [^{35}S]methionine failed to demonstrate synthesis of GP IIb or IIIa. Additionally, no GP IIb or IIIa was detected when immunoisolation was carried out in pure preparations of monocytes containing <1:100 platelet-monocyte ratios and SDS acrylamide gels were stained by the sensitive silver stain method. Furthermore, heterologous polyspecific antisera and two monoclonal antibody preparations against GPs IIb and IIIa, which bound to platelets, failed to bind to monocyte membranes. Thus, evidence was presented that indicated that monocytes do not synthesize platelet GPs IIb and IIIa and that detection of these molecules in blood monocyte preparations reflects platelet contamination.

© 1986 by Grune & Stratton, Inc.

PLATELET GLYCOPROTEINS IIb and IIIa (GPs IIb and IIIa) are major constituents of the platelet plasma membrane and form a complex (GP IIb/IIIa) that participates both in the binding of fibrinogen and in platelet aggregation.[1-3] GPs IIb and IIIa are significantly diminished or absent in patients with Glanzmann's thrombasthenia, a hereditary bleeding disorder characterized by defective platelet aggregation and fibrinogen binding.[4-6] Platelet GPs IIb and IIIa are synthesized by megakaryocytes and expressed since early stages of megakaryocytopoiesis.[7-11] Virtually all mature megakaryocytes, as well as early immature megakaryocytes (promegakaryoblasts) and the clonable megakaryocyte progenitors, bear these antigens.[7-10,12] In addition, recent reports suggest that monocytes may also express platelet GPs IIb and IIIa.[13-17] In this communication, studies were carried out to characterize the platelet GPs IIb and IIIa associated with blood monocytes and to determine whether monocytes synthesize these platelet glycoproteins. No monocyte synthesis of GPs IIb and IIIa was detectable. It was also shown that detection of GP IIb/IIIa in monocyte preparations was due to platelet contamination.

MATERIALS AND METHODS

Preparation of human mononuclear blood cells and platelets. Venous blood was collected from normal volunteers in 0.32% sodium citrate or 5 mmol/L EDTA (final concentration) in polypropylene test tubes. For experiments requiring full platelet depletion, EDTA anticoagulated blood was diluted in equal volumes of 0.3 mmol/L EDTA calcium- and magnesium-free Hanks' balanced salt solution (GIBCO, Grand Island, NY) containing 1.25×10^{-5} mol/L sodium citrate, 2.52×10^{-5} mol/L HEPES buffer, and 4.1×10^{-6} mol/L sodium bicarbonate at pH 7.0 (HBSS/C) and centrifuged at 1,135 g for 15 minutes at 4 °C. The buffy coat was collected and processed by sequential differential centrifugations at 4 °C.[18,19] Mononuclear cell preparations were obtained from leukocyte concentrates depleted of erythrocytes and platelets by buoyant density centrifugation on gradients generated with solutions of colloidal silica particles coated with polyvinyl pyrollidone (Percoll, Pharmacia Fine Chemicals, Piscataway, NJ) in HBSS/C containing 0.3 mmol/L EDTA at 22 °C. Cells harvested from the interface of the gradient layers (d < 1.077 g/cm^3) were subsequently processed through four to five cycles of incubations with autologous serum containing 5 mmol/L EDTA and intervening differential centrifugations, as described by Pawlowski et al.[20] Platelet contamination was evaluated by microscopic examination of cell suspensions and Wright-Giemsa–stained smears.

For experiments in which the testing populations contained various platelet-nucleated cell ratios, buffy coats and platelet-rich plasma were generated from citrated venous blood and processed independently. In these experiments, gradients were designed to maximize monocyte enrichment, and cells were resuspended directly in gradient solutions. After centrifugation, low-density mononuclear cells of buoyant densities <1.077 g/cm^3 were collected from the upper medium layer and the gradient interface. Cells from the gradient layer (d = 1.077 g/cm^3), which were primarily lymphocytes, were selectively excluded. Washed platelets were obtained from platelet-rich plasma as described elsewhere.[7] Platelets were resuspended in Tris–HCl–citrate buffer at pH 6.4 containing 63 mmol/L Tris, 95 mmol/L NaCl, 5 mmol/L KCl, and 12 mmol/L citric acid and stored at 37 °C in polypropylene tubes. Before reconstitution, platelet counts were performed with a Coulter counter (Model ZBI; Coulter Electronics, Hialeah, Fla).

Gel-filtered platelets were prepared by passage of citrated platelet-rich plasma through Sepharose 2B equilibrated in HEPES-

buffered Tyrode's solution containing 3.8 mmol/L HEPES, 3.8 mmol/L NaH_2PO_4, 137 mmol/L NaCl, 2.7 mmol/L KCl, 1 mmol/L $MgCl_2$, 0.2% BSA, and 0.1% dextrose at pH 7.35, as described elsewhere.[19]

Antisera. Monospecific rabbit antisera against purified human platelet GPs Ib, IIb, and IIIa, and polyspecific rabbit antiplatelet membrane antisera were prepared and tested for specificity as described previously.[21-23] Monoclonal antibody PC-1 with specific reactivity to the platelet GP IIb/IIIa complex was generated and screened as described elsewhere.[12] Polyspecific rabbit antimouse Fab Ig was a generous gift from Dr Howard Grey (National Jewish Hospital, Denver). IgG fractions of all rabbit and mouse antisera were prepared by 50% saturated ammonium sulfate precipitation, DEAE-cellulose chromatography, and, subsequently, conjugated to fluorescein isothiocyanate (FITC) or tetramethylrhodamine isothiocyanate (TRITC) (BBL Microbiology Systems, Walkersville, Md).[7] The conjugated proteins were fractionated by column chromatography on DEAE-cellulose, using stepwise elution with sodium phosphate buffers, pH 7.4, of 0.01, 0.05, and 0.1 mol/L. In general, 0.05 mol/L sodium phosphate buffer eluted antibody preparations with a dye-protein molar ratio of 1 ± 0.3 and was found to have the highest specific staining activity. Additionally, a monoclonal antibody against platelet GP Ib was kindly provided by Dr Barry Coller (SUNY, Stonybrook, NY).[24] Monoclonal antibodies B1, T3/T11, and Mol, with specific reactivities against B lymphocytes, T lymphocytes, and monocytes, respectively, were purchased from Coulter Immunology (Hialeah, Fla). Rabbit IgM antimouse IgG used to enhance complement fixation in the cytolytic assay was prepared by short-term immunization and subsequent precipitation and chromatography as described previously.[12]

Radioiodination of membrane proteins. Cell surface proteins on mononuclear blood cells and washed platelets were radioiodinated with ^{125}I by the tetrachloro-diphenylglycoluril method (Iodo-Gen, Pierce Chemical Co, Rockford, Ill).[25] Briefly, 5×10^6 mononuclear cells or 2×10^9 platelets resuspended in 200 μL phosphate-buffered saline (PBS) were incubated with 100 μCi of ^{125}I in the presence of 250 μg 1,3,4,6-tetrachloro-3α,6α-diphenylglycoluril (Iodo-Gen) for ten minutes at 22 °C. Tubes were precoated with 250 μg of Iodo-Gen dissolved in 125 μL chloroform under gentle stream of nitrogen. After iodination, unbound ^{125}I was removed by washing cells three times with PBS, and cells were solubilized as described later.

Metabolic labeling of mononuclear cells and platelets. Aliquots of isolated blood mononuclear cells (40×10^6) or platelets (1×10^9) resuspended in 1 mL methionine-free minimum essential medium (MEM)/Eagle supplemented with 0.015 mol/L L-glutamine, 5% whole fetal calf serum (FCS), and 10% methionine-free FCS were pulse-labeled with 400 μCi [^{35}S]methionine (1,100 Ci/mmol) at 37 °C for four hours. FCS was heat-inactivated at 56 °C for 30 minutes. Methionine-free FCS was prepared by extensive dialysis against methionine-free MEM. Unbound label was removed by washing cells, and homogenates of cell proteins were generated by solubilizing cells with 1% Triton X-100 in the presence of 2 mmol/L phenlymethylsulfonylfluoride, 5 mmol/L *N*-ethylmaleimide, 10 mmol/L EDTA (all from Sigma Chemical Co, St Louis) and 1 μmol/L pepstatin (Protein Foundation, Osaka, Japan). Validation of endogenous incorporation of radioactive amino acids into neosynthesized protein was obtained by pusle-labeling cells in the presence of increasing concentrations of the protein synthesis inhibitor cycloheximide as well as by evaluating radioactive label incorporation into TCA-precipitable protein.

Immunoprecipitation, SDS gel electrophoresis, and fluorography. Homogenates of mononuclear cells and platelets were subjected to solid-phase immunoadsorption with protein A-Sepharose CL-4B beads (Pharmacia) coated with antibodies monospecific for platelet GPs IIb and IIIa after extensive preclearing. Binding efficiency of antibody to protein A-Sepharose CL-4B beads was between 17 and 19 μg/μL beads. Binding efficiency of a radioiodinated antibody preparation was estimated by measuring radioactivity bound to washed beads over specific labeling activity expressed in cpm/μg protein. The efficiency of the immunoprecipitation system used was estimated by measuring removal of GP IIb/IIIa from a radioiodinated platelet membrane preparation. Assessment of antigen precipitation was conducted on platelet lysates by sequential adsorptions with antibody-coated beads. In a representative experiment, 255 μg antibody coupled to 15 μL beads removed all GP IIb/IIIa derived from a lysate of 2×10^9 platelets detectable by autoradiography. Preclearing was performed by sequential incubation of lysates with immunoadsorbant beads and beads coated with normal rabbit or mouse IgG. After incubation of cell homogenates for four to six hours at 4 °C with rotation, immunobeads were washed three times with 20 mmol/L Tris-HCl containing 500 mmol/L NaCl and 1% ovalbumin (pH 7.8) and three times with 20 mmol/L Tris-HCl containing 150 mmol/L NaCl (pH 7.8). Subsequently, immobilized protein was eluted by incubation of beads in 20 mmol/L Tris-HCl containing 2% SDS and 6 mol/L urea (pH 6.8) for five minutes at 100 °C. Eluants were subjected to 7.5% SDS-polyacrylamide gel electrophoresis (PAGE) under reducing and nonreducing conditions.[26,27] Gels were subsequently examined for immunoisolated proteins after processing for fluorography, silver stain, or Coomassie blue staining with estimated levels of sensitivity of approximately 1 to 10 pg, 1 to 5 ng, and 0.5 to 1 μg protein, respectively.[27-30]

Immunofluorescence assays, flow cytometry, and cell sorting. For fluorescence staining of membrane-restricted components, isolated cells were incubated with 20 to 50 μL of various antibody preparations in the presence of PBS containing 0.02% sodium azide (NaN_3) and 2% bovine serum albumin (BSA). After incubation at 4 °C for 30 minutes, cells were washed twice in PBS–BSA–NaN_3 and examined with Ploem illuminator and phase-contrast optics or processed by flow cytometry. To block functionally the Fc region of IgG molecules, antibody preparations were pretreated with *Staphylococcus aureus* protein A at wt-wt ratios of 7:1. $F(ab')_2$ fragments of second antibodies were also used. For fluorescence staining, smears of the various types of cell preparations were fixed with pure methanol at room temperature for 15 minutes, washed with PBS three times, and incubated with the different antibody preparations in a wet chamber at 20 °C for 30 minutes. After washing twice in PBS, cells were examined by ultraviolet microscopy. Cells were double-assayed for two antigens by staining cell preparations simultaneously or sequentially with a TRITC-conjugated antiserum or an FITC-conjugated specific reagent.[8]

Flow cytometric analysis was performed with a Coulter EPICS V (Coulter Electronics) equipped with Coherent 94-S argon ion laser. Cells in suspension were excited with laser adjusted to 1 W at 488 nm for FITC and 514 nm for TRITC at a flow rate of approximately 1,500 to 3,200 cells per second using a 76-μ flow tip. Sorting of cell subpopulations was performed using both green fluorescence and forward angle light scatter after defining appropriate electronic windows. To assess the effectiveness of the sorting procedure, positively sorted cells were reanalyzed by flow cytometry and phase-contrast microscopy for expression of Mo-1 antigen and latex particle phagocytosis, respectively. Data were analyzed with a Coulter EASY data-processing computer.

Complement-mediated cytolysis. Preparations of mononuclear cells depleted of most free-floating platelets were washed twice in McCoy's 5-A medium. Aliquots of 3×10^6 cells were incubated with 375 μL of monospecific antisera or ammonium sulfate precipitated mouse monoclonal antibody preparations at various concentrations for 30 minutes at room temperature and, subsequently, washed twice in McCoy's 5-A medium containing 10% heat-inactivated fetal bovine serum. Antibody-treated cells were then resuspended in 375 μL undiluted oxidized normal human AB Rh_D+ serum that was prepared by iodination and used as a source of complement, and incubated at 37 °C for 30 minutes.[31] To enhance complement fixation by monoclonal antibodies, antibody-treated cells were incubated with a rabbit IgM antimouse IgG at room temperature for 30 minutes and washed twice before complement treatment. Cell viability was assessed by supravital staining with trypan blue and observation under phase-contrast microscopy.

RESULTS

Immunoisolation of platelet glycoproteins IIb and IIIa from low-density human mononuclear blood cell preparations. The presence of platelet GPs IIb and IIIa in monocytes was investigated in preparations of low-density mononuclear cells generated after depletion of free-floating platelets. Typically, the mononuclear cell preparations contained approximately 56% monocytes and 44% lymphocytes. Cell differential analyses were performed by immunofluorescence using monoclonal antibodies Mol, B1, and T11/T3 specific for monocytes and B and T lymphocytes, respectively. Platelet-monocyte ratios, reflecting platelet contamination, were determined by examination of cell suspensions under phase-contrast microscopy and differential analyses of Wright-Giemsa–stained smears. Mononuclear cell homogenates were subjected to immunoisolation using protein A-Sepharose beads coated with rabbit antibodies monospecific for GPs IIb and IIIa. Two bands of approximately 126,000 and 116,000 daltons, corresponding to the molecular weights of reduced platelet GPs IIb and IIIa, were clearly identified in SDS gels of reduced immunoisolated material obtained from a cell preparation of 20 × 10^6 mononuclear cells containing 11 × 10^6 monocytes and 3.26 × 10^8 platelets (platelet-monocyte ratio = 30) (Fig 1B). Visualization of the nonreduced monomeric GPs IIb and IIIa molecules was precluded by the heavily stained band of the antibodies' IgG molecules (Fig 1A). Parallel controls using normal rabbit IgG are depicted in Fig 1C and D.

The presence of platelet GPs IIb and IIIa in a cell preparation of 40 × 10^6 mononuclear cells containing 20 × 10^6 monocytes and 2.86 × 10^6 platelets (platelet-monocyte ratio = 0.14) was also investigated in immunoisolated material eluted from beads coated with rabbit antiplatelet GPs IIb and IIIa after radioiodinating cell membrane proteins by the chloroglycoluril method. Autoradiograms of immunoisolated material electrophoresed in 7.5% acrylamide SDS gels revealed trace amounts of GPs IIb and IIIa, which comigrated with clearly identifiable GPs IIb and IIIa isolated in parallel from platelets (data not shown).

Assessment of synthesis of platelet GPs IIb and IIIa by blood monocytes. To assess whether platelet GPs IIb and IIIa immunoisolated from low-density blood cells were platelet- or monocyte-derived, studies were conducted to investigate the biosynthesis of these proteins. These studies were undertaken with the expectation that platelets, unlike monocytes, have only rudimentary protein synthetic apparatuses, and that any newly synthesized protein would be monocyte-derived. In a series of experiments, monocyte preparations containing varying degrees of platelet contamination were metabolically labeled with [^{35}S]methionine and analyzed for the synthesis of GPs IIb and IIIa. Material immunoisolated using antiplatelet GP IIb and IIIa antisera was electrophoresed in 7.5% SDS gels and analyzed concurrently by fluorography and Coomassie blue staining. Immunoprecipitates isolated from a preparation of 80 × 10^6 mononuclear cells containing 40 × 10^6 monocytes and 8 × 10^9 platelets (platelet-monocyte ratio = 200) were analyzed under nonreducing and reducing conditions (Fig 2). Although two bands of 125,000 and 116,000 daltons were readily recognized in the reduced Coomassie blue stained gel (Fig 2B), no comparable proteins were observed in either the nonreduced or the reduced counterpart fluorograms (Fig 2A′ and B′).

In another experiment, a preparation of 80 × 10^6 mononuclear cells containing 40 × 10^6 monocytes and 1.48 × 10^8 platelets (platelet-monocyte ratio = 5) was studied in a similar manner and neither GP IIb nor IIIa was detected (data not shown). Material derived from the same immunoprecipitation when analyzed in gels loaded with ninefold increased amount of protein revealed that although a trace of protein was visualized in Coomassie blue stained gels (Fig 2D), no detectable neosynthesized GP IIb or IIIa was observed (Fig 2C′ and D′). The specificity of the metabolic labeling system of monocytes was established by pulsing cells in the presence of increasing concentrations of cycloheximide (Fig 3). Cycloheximide at a concentration of 1 mmol/L fully inhibited protein synthesis of 2 × 10^6 cells.

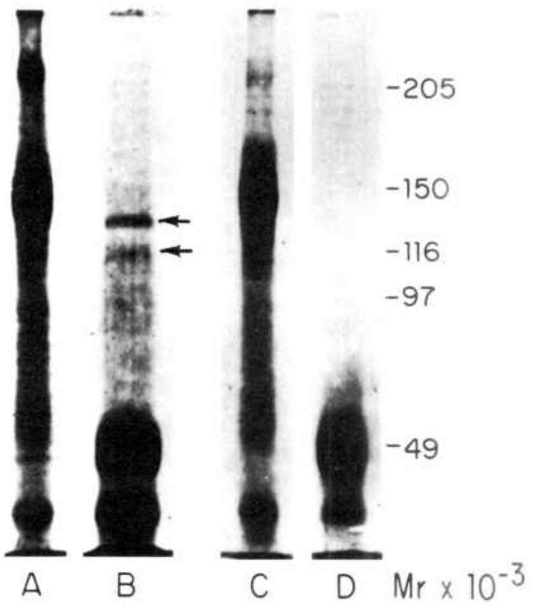

Fig 1. Electrophoretic analysis of platelet GPs IIb and IIIa immunoisolated from a mononuclear blood cell lysate solubilized in 5 mmol/L EDTA, 1% Triton X-100, 20 mmol/L Tris-HCl at pH 6.8 (nonreduced A, reduced B) in 7.5% acrylamide SDS gel stained with Coomassie blue. Arrows indicate immunoisolated GPs IIb and IIIa. Cell preparation contained 11 × 10^6 monocytes and 3.26 × 10^8 platelets (platelet-monocyte ratio = 30). Gels shown in C and D correspond to material eluted from control beads coated with normal rabbit IgG and electrophoresed under non-reducing and reducing conditions, respectively. Molecular markers are indicated at the right: myosin, 205,000 daltons; immunoglobulin G, 150,000; β-galactosidase, 116,000; phosphorylase B, 97,000; egg albumin, 49,000.

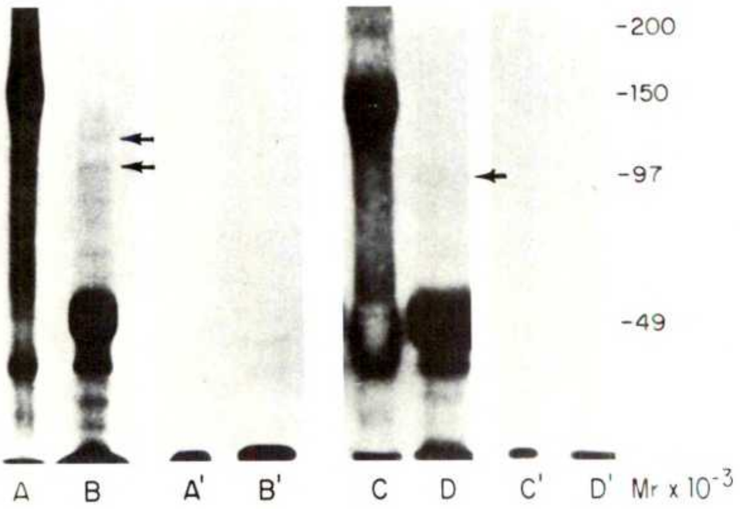

Fig 2. Eluants of [^{35}S]methionine-labeled mononuclear homogenates (platelet-monocyte ratio = 200) extracted from immunobeads coated with rabbit antiplatelet GPs IIb and IIIa analyzed concurrently by Coomassie blue staining (non-reduced A, reduced B) and fluorography (nonreduced A, reduced B) after 7.5% SDS-PAGE. Similar immunoisolated material obtained from preparations containing platelet-monocyte ratio = 5 (C, C' non-reduced, D, D' reduced). Arrows indicate immunoisolated GPs IIb and IIIa. Molecular markers are indicated on the right: myosin, 200,000 daltons; immunoglobulin G, 150,000; phosphorylase B, 97,000; egg albumin, 49,000.

GPs IIb and IIIa were studied in a highly pure preparation of monocytes obtained by flow cytometric sorting. Blood monocytes depleted of free-floating and most adherent platelets were stained using a fluorescent-labeled monoclonal antibody specific for a human monocyte cell surface antigen (mol wt 90/150 kd; Mol, the CR_3, or complement receptor type three) expressed on monocytes and absent in the majority of lymphoid cells (except natural killer cells) and platelets (Coulter Immunology).[32] Figure 4 shows the flow cytometric distribution of the mononuclear cell preparation as a function of the light-scattering and fluorescent intensity. The boxed image corresponds to selected sort windows that includes Mol-bearing monocytes. Flow cytometry provided a preparation of 3.36×10^6 monocytes, representing more than 98% nucleated cells, that contained 3.3×10^4 platelets (platelet-monocyte ratio = 1:100). The presence of GPs IIb and IIIa in sorted monocyte populations was investigated by SDS-PAGE of immunoisolated material. Electrophoretic analysis revealed that no platelet GPIIb or IIIa were detected in the cell preparation despite the fact that gels were stained by the sensitive silver stain method (data not shown).

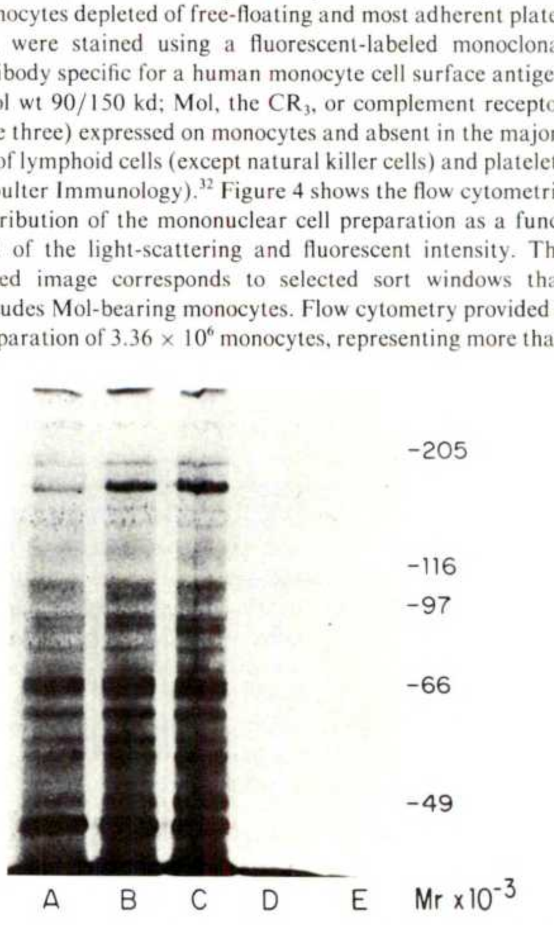

Fig 3. Fluorogram of protein homogenates obtained from mononuclear blood cells pulse-labeled with [^{35}S]methionine after electrophoresis in 7.5% acrylamide SDS gel under nonreducing conditions (A). (B), (C), (D), and (E) correspond to profile of radiolabeled proteins from cells pulsed in the presence of 1, 10, 100, and 1,000 μmol/L cycloheximide, respectively. Molecular markers are indicated on the right: myosin, 205,000 daltons; β-galactosidase, 116,000; phosphorylase B, 97,000; bovine serum albumin, 66,000; egg albumin, 49,000.

In order to exclude the synthesis of GPs IIb and IIIa by platelets, preparations of fully purified platelets were metabolically labeled and subjected to immunoadsorption in a similar manner. However, minimal specific labeling was detected corresponding to 3.9×10^{-5} TCA precipitable dpm/platelet, as compared with monocytes, which incorporated 1.805 dpm/cell when pulsed under the same conditions. Furthermore, increasing concentrations of cycloheximide resulted in inhibition of [^{35}S]methionine incorporation. More important, no neosynthesis of GP IIb or IIIa was detected when platelet homogenates were subjected to immunoprecipitation.

Identification of cells bearing platelet GPs IIb and IIIa in mononuclear cell preparations. The expression of platelet GPs IIb and IIIa on the membrane and in the intracellular compartment of isolated human blood cells was investigated by immunofluorescence using heterologous and monoclonal antibody preparations. For staining of membrane-restricted

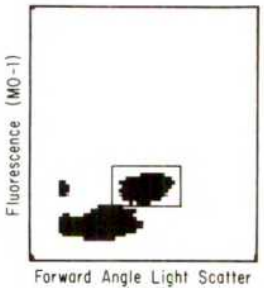

Fig 4. Two-dimensional flow cytometric distribution of mononuclear blood cells analyzed by forward angle light scatter (x) and binding of fluorescent-labeled Mol antibody (y). Boxed image indicates selected sort windows.

proteins, preparations of viable cells were incubated with specific antibody preparations. Staining of intracellular antigens was achieved by incubating cell preparations with antibody preparations after smearing and fixation, which rendered the membranes permeable to the antibody molecules. In mononuclear cell preparations obtained from 30 normal individuals, platelets were the only cell type stained for GPs IIb and IIIa. Monocytes were clearly not reactive with monospecific rabbit antisera against GP IIb or IIIa or two monoclonal antibodies specific for the platelet GP IIb/IIIa complex. Frequent significant fluorescence associated with mononuclear cells stained by immunofluorescence for GPs IIb and IIIa was attributable to platelets intimately associated with these cells. Figure 5 depicts mononuclear cell preparations stained for GP IIb/IIIa using monoclonal antibody preparation PC-1 (A and B) in which fluorescence staining is restricted to platelets (A′ and B′).

The expression of GPs IIb and IIIa by monocytes was studied further using complement-mediated cytotoxicity (Table 1). In this sensitive system, anti-Mol mediated the lysis of blood monocytes, but no monocyte cytolysis was observed with polyclonal and monoclonal antibodies to platelet GPs IIb, IIIa, or Ib or a heterologous polyspecific antiplatelet membrane preparation.

DISCUSSION

Studies described in this communication demonstrated that GPs IIb and IIIa associated with blood monocytes are derived from platelets. Previously, GP IIb/IIIa has been regarded as a restricted antigen for the megakaryocyte/platelet lineage.[8,18] However, the expression of GP IIb/IIIa by blood monocytes has been reported recently by several authors.[13,14,16] Preparations of blood monocytes with different degrees of platelet contamination were labeled in vitro with [^{35}S]methionine with the expectation that newly synthesized proteins would be monocyte-derived, since platelets contain only rudimentary protein synthetic systems.[33,34] Analyses of immunoisolated GPs IIb and IIIa from colabeled cultures of monocytes and platelets indicated that no GP IIb or IIIa was newly synthesized. On the other hand, substantial amounts of unlabeled GPs IIb and IIIa were detected and found to vary with the level of platelet contamination. The failure to detect synthesis of GP IIb or IIIa may be attributed to the lack of synthesis by mononuclear cells. Based on the 1 to 10 pg protein level of sensitivity described for fluorography,[27,28] in our system, monocytes could not have synthesized more than 0.076 to 0.76 GP IIb/IIIa molecules per monocyte. In addition, immunoprecipitated GP IIb/IIIa from mononuclear cells corresponded to about 9 to 18.5×10^{-6} of the total TCA precipitable material. Synthesis of GP IIb/IIIa, however, was demonstrated in human marrow megakaryocytes using the same experimental approach.[11] In 5×10^5 [^{35}S]methionine-labeled megakaryocytes, immunoprecipitated GP IIb/IIIa represented only 2×10^{-4} of all TCA precipitable counts, indicating that the detection system used was highly sensitive in detecting levels of approximately 0.01% to 0.02% of total precipitable counts.[11] Furthermore, while synthetic rates for specific proteins have not been determined in the mononuclear cell preparations studied, synthesis of an array of proteins inhibitable by cycloheximide was observed.

Studies conducted by several groups have demonstrated that platelets contain vestigial amounts of mRNA and may be capable of minimal protein synthesis.[35] In our studies using gel-filtered platelets and [^{35}S]methionine with high specific activity, we have detected trace amounts of protein synthesis comparable 1/10,000 of the specific incorporation observed in other blood cell types. However, attempts to immunoisolate metabolically labeled GPs IIb and IIIa from postculture preparations of gel-filtered or washed platelets failed to demonstrate neosynthesis of these antigens.

Immunofluorescence studies detecting GP IIb and IIIa molecules in blood monocyte preparations revealed that staining was restricted to platelets. Similarly, only platelets and megakaryocytes were stained in a series of 45 immunofluorescence analyses of peripheral blood and bone marrow

Table 1. Detection of Cell Membrane Antigens on Blood Monocytes by Complement-Mediated Cytolysis

Antibody Preparation	Mononuclear Cells Killed (%)
Polyspecific antiplatelet membrane	3
Heterologous antiplatelet GP IIb/IIIa	<1
Monoclonal antiplatelet GP IIb/IIIa (PC-1)	1
Heterologous antiplatelet GP Ib	<1
Monoclonal antiplatelet GP Ib	<1
Monoclonal anti-Mol	39
Normal rabbit IgG	<1
Normal mouse IgG	<1
Rabbit IgM antimouse IgG	3
Complement	2
Medium	1

Cytotoxicity was performed using a two-step assay (heterologous rabbit antiserum + complement) or a three-step assay (monoclonal antibody + rabbit IgM antimouse IgG + complement). Monocytes represented approximately 40% of the low-density mononuclear blood cells ($d < 1.077$ g/cm^3). Cell viability was assessed by trypan blue exclusion.

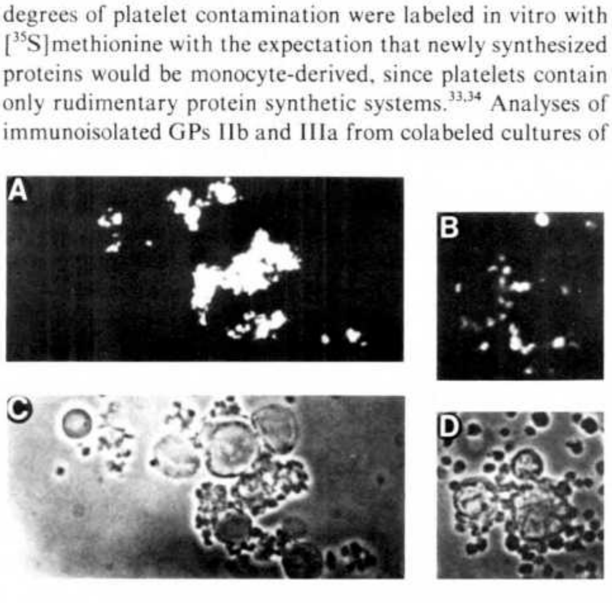

Fig 5. (A through D) Mononuclear blood cells stained by immunofluorescence after fixation with monoclonal antibody PC-1 specific for platelet GP IIb/IIIa and TRITC rabbit antimouse Fab Ig. Fluorescent panels (a and b) and phase-contrast counterparts (a′ and b′) demonstrate restriction of immunofluorescence staining to platelets (×595).

cell preparations using heterologous antisera monospecific for GPs IIb and IIIa as well as two monoclonal antibodies specific for the platelet GP IIb/IIIa complex. Furthermore, GPs IIb and IIIa present in mononuclear cell preparations failed to trigger complement-mediated lysis of monocytes in assays using heterologous and monoclonal antibodies specific for these antigens, indicating that these molecules were not integrally associated with monocyte plasma membranes.

Previously, Gogstad et al[13] have reported the detection of an antigen immunologically indistinguishable from the platelet GP IIb/IIIa complex in blood monocytes. In crossed immunoelectrophoretic analyses of preparations of solubilized monocyte membranes using a monospecific antiserum to the GP IIb/IIIa complex, Gogstad and associates demonstrated a single immunoprecipitate representing this molecular entity. However, adherent monocytes isolated by conventional techniques after full depletion of free-floating platelets typically have at least three to five platelets specifically bound to their surfaces and appear to represent the source of platelet GPs IIb and IIIa detected by Gogstad et al.[13] Moreover, their observation that no monocyte-associated GP IIb/IIIa was detectable in cells in a patient homozygous for Glanzmann's thrombasthenia does not clarify its source. Detection of the platelet GP IIb/IIIa complex in mononuclear cell preparations using a monoclonal antibody has been reported by Burckhardt et al.[14] However, high levels of platelet contamination are inferred from their experimental protocol. Removal of platelets adhered to monocytes requires extensive, repeated incubations with solutions containing an excess of 5 mmol/L EDTA and intervening differential centrifugations.[20] Isolation of platelet GPs IIb and IIIa from blood monocytes also has been reported by Bai et al[16] using two monoclonal antibody preparations against the GP IIb/IIIa complex. However, the mononuclear cell preparations were obtained from defibrinated peripheral blood, which is known to contain high concentrations of platelet microparticles.[36] Serum obtained from defibrinated blood contains platelet membrane fragments generated during cell activation with quantifiable levels of platelet proteins, including platelet GPs Ib, IIb, and IIIa, as well as platelet factor 4.[36] The description by Bai et al that GP Ib was readily recognized in their monocyte preparations is puzzling. Using the same monoclonal antibody (AN-51), other laboratories have not detected monocyte-associated GP Ib, suggesting that its presence may indeed represent contamination by platelet-derived proteins.[37] Expression of platelet GP IIb/IIIa by an erytholeukemia-derived cell line, K-562, expressing multilineage phenotypes, has been reported by Gewirtz et al[15] and Tabilio et al.[17] However, using the same and different antibody preparations, other authors failed to detect GPs IIb and IIIa in K-562 cells, indicating that gene expression of these antigens in neoplastic hematopoietic cell lines may be erratic.[38] HEL cell line established from a patient with Hodgkin's disease who later developed an erythroleukemia also expressed GPs IIb and IIIa.[39] Two other cell lines—U-937, derived from histiocytic lymphoma cells, and HL-60, from promyelocytes—have been reported to express GP IIb/IIIa.[14,16]

A number of similar and shared structural properties have been recognized between platelets and endothelial cells, including the expression of factor VIII:von Willebrand factor, fibronectin, thrombin receptors, and thrombospondin.[40-43] More recently, a GP IIIa-like molecule has been characterized in umbilical vein endothelial cells using a monoclonal antibody preparation.[44] Intriguingly, no GP IIb was co-isolated with this GP IIIa-like molecule, suggesting that certain differences exist between this new entity and the classical GP IIb/IIIa complex, as identified on platelets and megakaryocytes.[6] Structural homology between platelet GP IIIa and its endothelial analog may reflect common physiological functions or may be due to evolution from a common archetype.[45]

Characterization of GPs IIb and IIIa in normal hemopoietic cells by immunofluorescence have revealed that platelets and megakaryocytes are the only blood and marrow cell types expressing the GP IIb/IIIa complex.[7,8,10] The clonable progenitor for megakaryocytes (CFU-Mk)—but not the progenitors for the multilineage colonies (CFU-GEMM), erythroid (BFU-E), or the myelomonocytic (CFU-GM) lineages—contain the GP IIb/IIIa complex.[12] Additionally, synthesis of GPs IIb and IIIa with similar molecular characteristics as their platelet counterparts has been demonstrated in isolated human marrow megakaryocytes, thereby establishing the source of these glycoproteins in platelets.[11]

ACKNOWLEDGMENT

We thank Leela Jashnani for her excellent technical assistance, Ira Schieren (Cornell University Medical College Flow Cytometry Unit) for performing flow cytometric analyses and cell sorting, and Dr Ralph Nachman for his helpful discussions and advice during the preparation of this manuscript.

Sulfhydryl Reducing Agents and Shape Regulation in Human Erythrocytes

By Hoai-Thu N. Truong, James E. Ferrell, Jr, and Wray H. Huestis

Metabolic crenation of red cells is reversible; on addition of nutrients, echinocytes recover the normal discoid shape. When the shape recovery takes place in the presence of reducing agents such as dithiothreitol (DTT), morphological change continues until the cells are stomatocytic. The degree of stomatocytosis varies, depending on the cell morphology when the nutrients and reducing agent are added. DTT has minimal effect on the shape of normal discocytes, but in its presence, mildly echinocytic cells become slightly cupped and advanced-stage echinocytes become severely stomatocytic. DTT must be present continuously for development and retention of stomatocytosis; echinocytes preincubated with or metabolically depleted in DTT do not become stomatocytic when supplemented in the absence of DTT, and DTT-induced stomatocytes revert to discocytes when the reducing agent is removed. DTT has no effect on adenosine triphosphate synthesis or equilibrium cell glutathione levels, and the induced stomatocytosis is not inhibited by excluding oxygen from cells during depletion. Spectrin phosphorylation and phosphate turnover are not affected by DTT. The echinocyte-to-discocyte transformation coincides with phosphorylation of membrane inner monolayer lipids (diacylglycerol to phosphatidic acid and phosphatidylinositol to phosphatidylinositol-4,5-bisphosphate). Overphosphorylation of these phospholipids is not responsible for the exaggerated shape recovery seen with reducing agents; phosphorylation of inner monolayer lipids proceeds identically in the presence and absence of DTT.

THE NORMAL DISCOID SHAPE of the human erythrocyte can be altered in vitro by metabolic depletion,[1] calcium loading,[2] or addition of a variety of amphipathic agents.[3] Control of normal cell shape has been attributed to the protein cytoskeleton that laminates the cytoplasmic face of the membrane,[4,5] with the suggestion that phosphorylation and dephosphorylation of spectrin could be the mechanism by which the cell regulates its morphology.[6,7] While an intact cytoskeleton is necessary for shape changes to occur,[8] recent work suggests that its role is passive[9,10] in that it adopts the conformation imposed by the bilayer.

Another model for control of red cell shape is the bilayer couple hypothesis,[11] which attributes cell shape changes to alterations in the relative areas of the inner and outer monolayers of the cell membrane. Any event or external agent that causes the outer monolayer to expand relative to the inner monolayer produces spiked spheres, echinocytes. Likewise, preferential expansion of the inner leaflet results in formation of cupped cells and spheres with invaginations (stomatocytes), species that appear to be the reverse of echinocytes. Agents that induce stomatocytosis can reverse the effects of echinocytic agents and vice versa.

Metabolic crenation is thought to result from bilayer imbalance secondary to dephosphorylation of phosphatidylinositol-4,5-bisphosphate and phosphatidic acid.[12] This crenation eventually becomes irreversible, but for many hours after adenosine triphosphate (ATP) depletion, addition of nutrients will induce echinocytes to revert to discocytes. The shape recovery coincides with phosphorylation of inner-membrane phospholipids that were dephosphorylated during crenation.[12,13]

Palek et al[14] report that the reducing agent dithiothreitol accelerates the shape recovery of metabolically crenated cells, perhaps by reducing cross-linked cytoskeletal elements. In this paper, we report that DTT and other reducing agents effect further shape changes in intact cells, inducing them to form stomatocytes rather than reaching a stable discoid shape. The biochemical consequences of such reduction are examined.

MATERIALS AND METHODS

Blood was obtained from healthy adult volunteers by venipuncture and collected in EDTA, heparin, or citrate anticoagulant. Erythrocytes were separated from plasma and buffy coat by centrifugation at 1,800 g for five minutes and washed three times in 4 vol of 150 mmol/L NaCl. Cells were used within six hours of being drawn. If the erythrocytes were not used immediately after washing, they were suspended in 138 mmol/L NaCl, 5 mmol/L KCl, 1.4 mmol/L NaH_2PO_4, 6.1 mmol/L Na_2HPO_4, 1 mmol/L $MgSO_4$, 5 mmol/L glucose, pH 7.4, and stored at 4 °C. Such cells were washed once in 150 mmol/L NaCl immediately before the experiment.

$[^{32}P]H_3PO_4$ (carrier-free) was purchased from ICN Radiochemicals (Irvine, Calif). Penicillin G was from Pfizer (New York). Luciferin, luciferase, 3,3'-dithiobis(6-nitrobenzoic acid) (DTNB), and DTT were obtained from Calbiochem-Behring (La Jolla, Calif). DTT was also purchased from Sigma (St Louis), which was the source of all other biochemicals. Other chemicals, obtained from J.T. Baker Chemical Co (Phillipsburg, NJ) or Fischer Scientific Co (Pittsburgh), were of at least reagent grade.

Film for autoradiography was obtained from Eastman Kodak Co (Rochester, NY); Cronex Lightning Plus intensifying screens were from DuPont Instruments (Wilmington, Del). Silica Gel HL plates were purchased from Analtech Inc (Newark, Del).

Metabolic Depletion and Reversal

All incubations were carried out at 37 °C in capped plastic tubes. The incubation buffers contained 100 μg/mL penicillin and 100 μg/mL streptomycin to retard bacterial growth. To induce ATP depletion and crenation, cells were incubated in 4 vol of 150 mmol/L NaCl, 7.5 mmol/L Na_2HPO_4, pH 7.4, at 22 °C ($NaCl/P_i$). Anaerobic depletion was carried out in sealed tubes containing humidified N_2. The inert gas was bubbled through the cell suspension every ten hours or when tubes were opened for sampling, whichever was more frequent.

Shape recovery was effected by resuspending the pelleted echinocytes in 4 vol of 138 mmol/L NaCl, 5 mmol/L KCl, 1.4 mmol/L NaH_2PO_4, 6.1 mmol/L Na_2HPO_4, 1 mmol/L $MgSO_4$, 5 mmol/L

Blood, Vol 67, No 1 (January), 1986: pp 214-221

glucose, pH 7.4, supplemented with an additional 5 mmol/L glucose, 10 mmol/L inosine, and 1 mmol/L adenosine (supplemented NaCl/P_i). Stomatocyte formation was induced by adding DTT at a concentration of 10 mmol/L unless otherwise noted.

In some experiments, crenated cells were diluted to a hematocrit of 10% with NaCl/P_i and *N*-tosyl-L-phenylalanine chloromethyl ketone (TosPheCH$_2$Cl, 200 mmol/L in dimethylsulfoxide) was added to yield a final concentration of 0.4 mmol/L. Control cells were treated similarly with dimethylsulfoxide alone.

In spectrin phosphorylation experiments, cells were prelabeled in 1 vol of 10 mmol/L *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES), 1 mmol/L MgSO$_4$, 1 mmol/L K$_2$HPO$_4$, 5 mmol/L KCl, 137 mmol/L NaCl plus 50 μCi/mL [^{32}P]H$_3$PO$_4$ (HEPES/$^{32}P_i$), supplemented with 10 mmol/L inosine, 10 mmol/L glucose, and 1 mmol/L adenosine. After ten hours the suspension was replenished with 10 mmol/L inosine, 10 mmol/L glucose, and 1 mmol/L adenosine. After 23 hours' incubation, by which time the amount of ^{32}P in spectrin reaches a steady state,[15] cells were pelleted, resuspended in HEPES/$^{32}P_i$ of the same specific activity, and allowed to deplete metabolically. Reversal of metabolic depletion was carried out in the same HEPES/$^{32}P_i$, supplemented with sugars. Turnover and rephosphorylation of spectrin were examined in cells depleted in ^{32}P-free NaCl/P_i and resuspended in supplemented HEPES/$^{32}P_i$.

In lipid phosphorylation experiments, cells were labeled with ^{32}P by depleting them in 1 vol of NaCl/P_i plus 150 μCi/mL [^{32}P]H$_3$PO$_4$. After approximately 24 hours of incubation at 37 °C, the cell suspension was diluted into 10 mmol/L Tris, 150 mmol/L NaCl (pH 7.4 at 22 °C), 10 mmol/L glucose, 10 mmol/L inosine, and 1 mmol/L adenosine to give a final hematocrit of 20%.

Assay Procedures

Morphology. Erythrocytes were diluted to a hematocrit of 5% and fixed in 150 mmol/L NaCl containing 0.5% glutaraldehyde. Cells were examined by bright field microscopy at a magnification of ×500. Stomatocytes were assigned a score of -4 to -1,[16] discocytes a score of 0, and echinocytes a score of $+1$ to $+5$.[12] The average score for a field of 100 cells was called its morphological index (MI).[17] Some fixed cell samples were washed with distilled water, placed on glass coverslips, air-dried, and examined by scanning electron microscopy.

Adenosine triphosphate. Frozen aliquots of cell suspension (50 μL) were diluted in 2.45 mL 150 mmol/L NaCl, boiled for 15 minutes, and centrifuged to clarity. The supernatant (undiluted or diluted 1:10) was assayed for ATP by the luciferin-luciferase method.[18]

Reduced glutathione. Reduced glutathione was measured by the DTNB reagent method[19] on frozen acid lysate of cells, unless otherwise noted. When present, DTT was removed from cell suspensions by repeated washing to remove the DTT, which also reacts with DTNB.

Spectrin phosphorylation. Aliquots (150 μL) of 20% cell suspension were lysed in 1.2 mL 10 mmol/L Tris, 2 mmol/L EDTA, pH 7.5, at 22 °C immediately after removal from incubation. The stroma were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis on 5% slab gels.[20] Autoradiograms of the dried gels were obtained by one-day exposures to Kodak X-OMAT AR film with intensifying screens. Individual bands of the gels were cut out, dissolved in 1 mL 30% H$_2$O$_2$ at 60 °C for nine to 24 hours, and analyzed by liquid scintillation counting. Results were normalized to the amount of protein loaded onto the gel, as determined by the Lowry assay.[21]

Lipids. Aliquots (100 μL) of cell suspension were removed during the shape recovery and stored frozen. Phosphatidylinositol-4-phosphate, phosphatidylinositol-4,5-bisphosphate, and phosphatidic acid levels were measured as described previously.[12] The frozen aliquots were lysed in 2 mL cold 10 mmol/L Tris, 2 mmol/L EDTA (pH 7.5 at 22 °C) and washed once in the same buffer. The pellet was extracted with 1.8 mL methanol/chloroform/concentrated HCl, 100:50:1 (vol:vol:vol), followed by water (0.6 mL) and chloroform (0.6 mL). Aliquots (0.7 mL) from the organic phase were dried under a stream of N$_2$ and redissolved in three 5-μL portions of chloroform. Lipids were separated by thin-layer chromatography on nonactivated 2.5 × 10-cm plates in 48:40:10:5 (vol:vol) methanol/chloroform/H$_2$O/ concentrated NH$_3$. Lipid spots were detected by iodine vapor and autoradiography. ^{32}P-labeled phospholipids were quantified by liquid scintillation counting of scraped spots.

RESULTS

Erythrocytes were incubated in NaCl/P_i to effect metabolic depletion. As shown previously,[1,12] ATP depletion proceeded with a half time of five to ten hours and was followed by metabolic crenation. Metabolically depleted echinocytes (Fig 1A) were pelleted and resuspended in sugar supplemented NaCl/P_i. ATP levels were partially restored and the cells recovered normal discoid shape, remaining in this configuration for many hours as long as nutrients were available (Fig 1B and Fig 2). DTT altered this shape recovery dramatically. In the presence of 10 mmol/L DTT, echinocytes quickly recovered discoid shape and then became cupped and invaginated stomatocytes (Fig 1C and Fig 2). The extent of the morphological overshoot depended on the original extent of crenation. Stage 1 echinocytes attained a slightly cupped shape, while severely crenated cells eventually developed the membrane invaginations of advanced-stage stomatocytes (Fig 3A). Similarly, if echinocytes had partially recovered toward discoid shape before addition of the reducing agent, the extent of DTT-induced stomatocytosis diminished (Fig 3B).

Other sulfhydryl reducing agents also induced stomatocytosis in recovering echinocytes but to variable extents. Dithioerythritol produced effects similar to the DTT response and in the same concentration range. 2-Mercaptoethanol induced detectable but less severe stomatocytosis; even at concentrations greater than 50 mmol/L this reagent typically produced morphological indices no greater than -1.0 (data not shown). Echinocytes treated with sodium dithionite (Na$_2$S$_2$O$_4$, 10 mmol/L) did not recover discoid or stomatocytic morphologies in the presence of sugars; thus, some reducing agents inhibit even normal shape recovery.

The continuous presence of the reducing agent was required to generate and maintain stomatocytic morphologies. Echinocytes pretreated with DTT (10 mmol/L for two hours at 0 °C) and then washed free of DTT before nutrient supplementation recovered the normal discoid shape but did not cup (Fig 4A). Identical results were obtained with DTT pretreatment at 37 °C. When DTT-induced stomatocytes were washed free of the reducing agent, the cells slowly recovered discoid shape (Fig 4B).

The extent of induced stomatocytosis was dependent on the DTT concentration. At hematocrits of 5% and 20%, half-maximal stomatocytosis was obtained at DTT concentrations of 2 to 3 mmol/L (Fig 5A). The same concentration dependence was observed for cells beginning at different

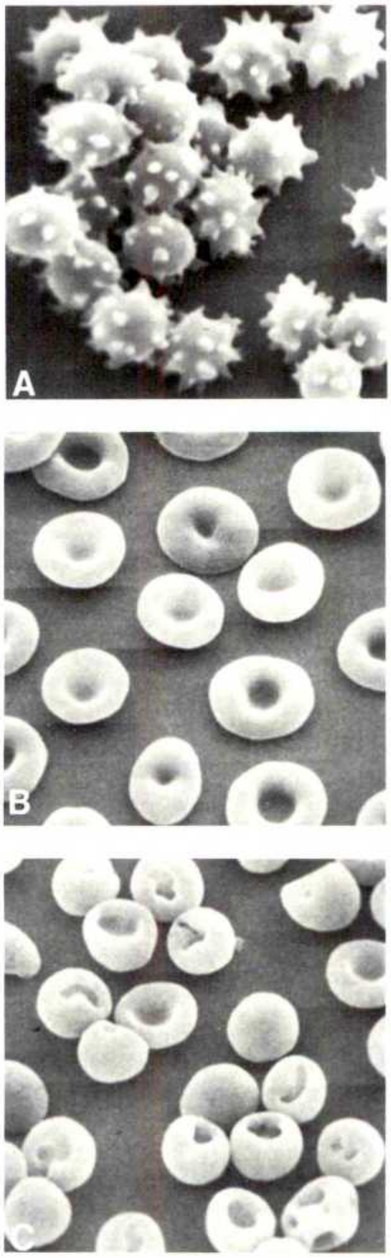

Fig 1. Scanning electron micrographs of (A) echinocytes formed by 21 hours of metabolic depletion; (B) discocytes obtained by incubating depleted cells for four hours in supplemented NaCl/P$_i$; (C) stomatocytes resulting from incubating depleted cells in supplemented NaCl/P$_i$ containing 10 mmol/L DTT. Original magnification ×3,000.

stages of crenation. At three points during metabolic depletion, cells were pelleted and resuspended in supplemented NaCl/P$_i$ with DTT at concentrations ranging from 0 mmol/L to 10 mmol/L. Half-maximal overshoot occurred at 2 to 3 mmol/L DTT with samples whose initial morphological indices were +0.9, +1.6, or +2.1 before supplementation (Fig 5B).

Oxidative damage. To examine the role of oxidative damage in DTT-induced stomatocytosis, cells were depleted under an inert atmosphere and in air. The inert atmosphere slowed glutathione depletion (Fig 6) but did not alter the rate of crenation. On sugar supplementation, erythrocytes depleted under an inert atmosphere recovered the normal discoid shape more rapidly than cells depleted under air, as reported previously.[14] When supplemented in the presence of DTT, cells depleted under both conditions formed stomatocytes at the same rate and to the same extent (Fig 7).

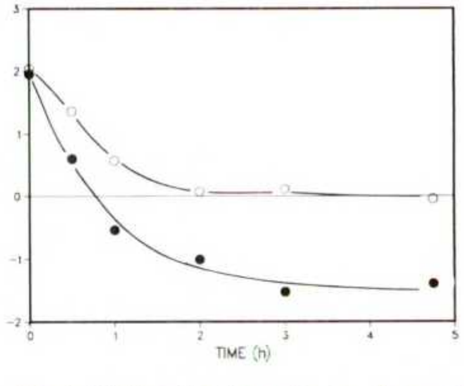

Fig 2. Effect of DTT on the shape recovery of crenated cells. Erythrocytes were metabolically depleted for 24 hours and then resuspended in supplemented NaCl/P$_i$ (○) or in supplemented NaCl/P$_i$ plus 10 mmol/L DTT (●).

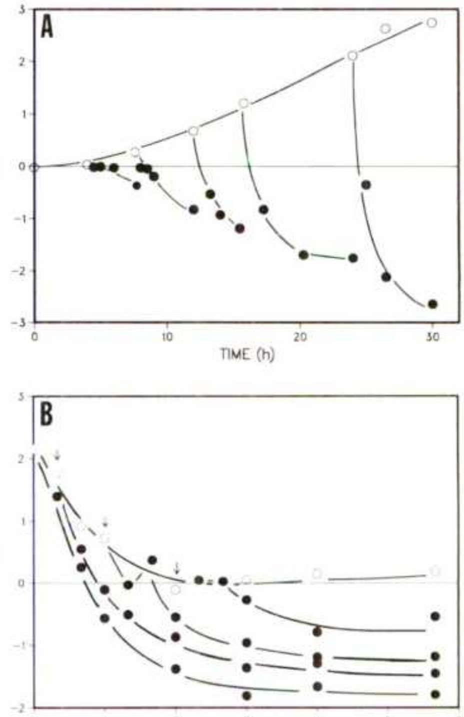

Fig 3. DTT-induced stomatocytosis at various stages of crenation. (A) Cells were metabolically depleted (○) in NaCl/P$_i$ + 10 mmol/L MgSO$_4$. At t = 4, 8, 12, 15.75, and 22 hours, aliquots were removed and incubated with supplemented buffer containing 10 mmol/L DTT (●). (B) Cells were metabolically depleted for 22 hours, pelleted, and then resuspended in supplemented NaCl/P$_i$ (○). At t = 0, 0.33, 0.67, 1, and 2 hours after resuspension, aliquots were removed and incubated with supplemented NaCl/P$_i$ containing 10 mmol/L DTT (●).

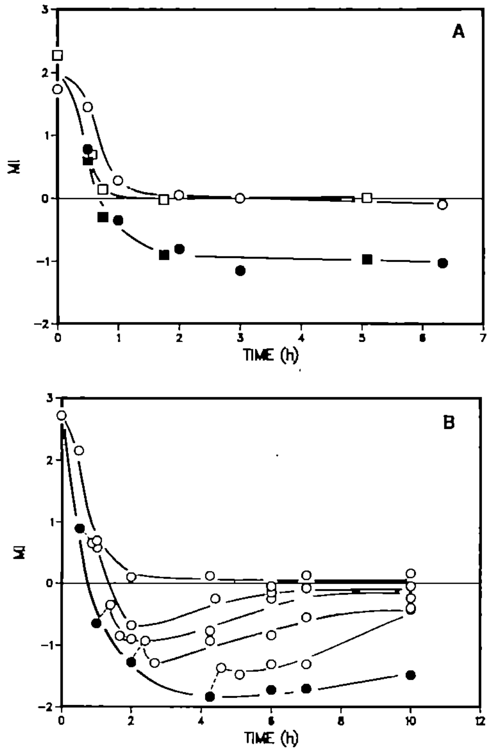

Fig 4. The continuous presence of DTT is required for stomatocytosis. (A) Cells were metabolically depleted for 24 hours. Cells were treated with 10 mmol/L DTT at 0 °C for two hours and washed repeatedly (□, ■) or not treated (O, ●). Cells were then resuspended in supplemented NaCl/P_i, without DTT (O, □) or with 10 mmol/L DTT (●, ■). (B) Erythrocytes were depleted for 23 hours and resuspended in supplemented NaCl/P_i without DTT (O) or with 10 mmol/L DTT (●). At t = 0.5, 1, 2, and 4.25 hours after resuspension in the DTT-containing buffer, aliquots were removed, washed extensively, and reincubated in DTT-free supplemented NaCl/P_i (O).

Similarly, cells depleted in 2 mmol/L DTT and then washed to remove the reducing agent recovered discoid shape. In the presence of additional DTT, they formed stomatocytes at the same rate and to the same extent as control cells (data not shown).

N-tosyl-L-phenylalanine chloromethyl ketone experiments. The chloromethyl ketone, TosPheCH$_2$Cl accelerates the shape recovery of echinocytes obtained by incubation with dinitrophenol.[22] TosPheCH$_2$Cl did not alter the shape recovery of metabolically crenated cells, but in its presence, DTT induced greater than normal stomatocytosis (Fig 8).

ATP and glutathione. Glutathione and ATP levels were assayed during shape recovery. ATP levels typically recovered to about 40% of their normal value, both in control and DTT-treated cells (Fig 9). Glutathione levels recovered to approximately 50% of the value found in fresh cells. DTT reduced all available oxidized glutathione within 20 minutes (the minimum time to prepare samples for the glutathione assay), but it had no effect on the final concentrations of reduced glutathione (Fig 9).

Spectrin phosphorylation. Spectrin, the major cytoskeletal protein, is phosphorylated in the band 2 subunit. The level of phosphorylation decreases after metabolic depletion and crenation and increases again when sugars are added.[15] Spectrin phosphorylation was not altered in echinocytes recovering in the presence of DTT. Cells prelabeled with ^{32}P were metabolically depleted and then resuspended in sugar

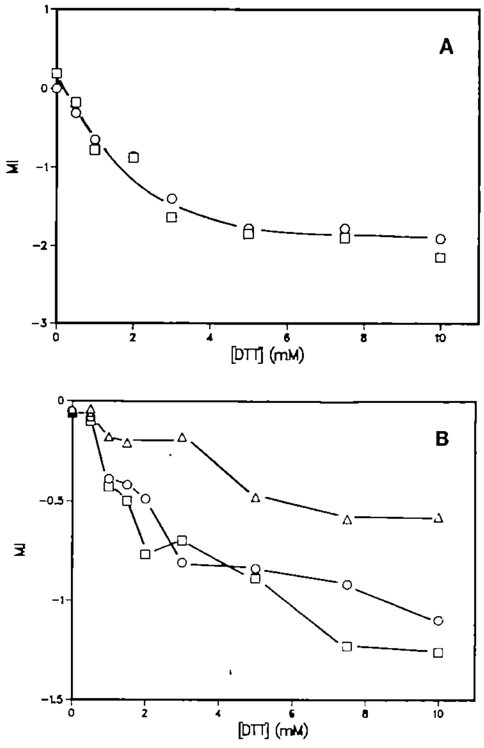

Fig 5. Concentration dependence of DTT stomatocytosis. (A) Effect of hematocrit. Cells were metabolically depleted for 21 hours, pelleted, and resuspended at a hematocrit of 5% (□) or 20% (O) in supplemented NaCl/P_i with [DTT] ranging from 0 to 10 mmol/L, and incubated for 4.5 hours. (B) Effect of degree of crenation. Cells were metabolically depleted. After 14 hours (MI = +0.9) (Δ), 21 hours (MI = +1.6) (O), and 24 hours (MI = +2.1) (□) of depletion, aliquots of crenated cells were removed, pelleted, resuspended at a hematocrit of 20% in supplemented NaCl/P_i with [DTT] ranging from 0 to 10 mmol/L, and reincubated for four hours.

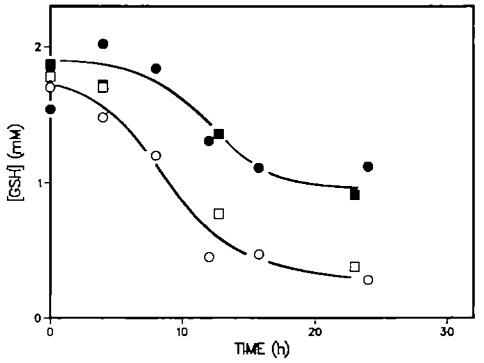

Fig 6. Glutathione levels during metabolic crenation under an inert atmosphere. Cells were depleted in air (O, □) or under humidified N_2 (●, ■). Data from two similar experiments are shown. Glutathione levels were measured on frozen cell suspensions.

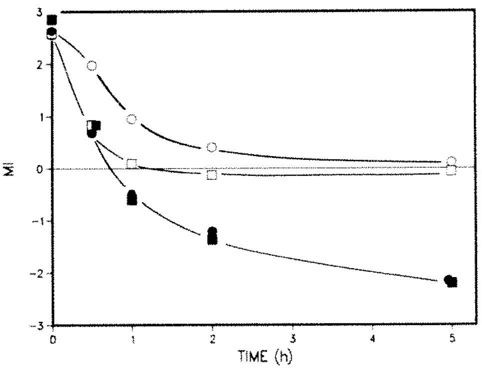

Fig 7. **Effect of prevention of oxidative damage during depletion. Cells were metabolically depleted in air (○, ●) or under N_2 (□, ■) for 23 hours and then incubated with sugar-supplemented medium with (●, ■) or without (○, □) 10 mmol/L DTT.**

supplemented buffer containing $^{32}P_i$ at the same specific activity as the buffer used for labeling and depleting the cells. DTT did not affect the rate or extent of spectrin phosphorylation (Fig 10A); thus, spectrin phosphate levels were not altered by the reducing agent. To determine whether spectrin phosphate turnover is linked to DTT-induced stomatocytosis, cells were metabolically depleted in ^{32}P-free buffer. The resulting echinocytes were resuspended in sugar-supplemented buffer containing ^{32}P. The ensuing incorporation of ^{32}P into spectrin should be due both to spectrin rephosphorylation and to turnover of residual phosphate groups. DTT had no effect on phosphate incorporation under these conditions (Fig 10B); thus, it does not alter the rate of turnover of spectrin phosphate.

Phosphoinositide and diacylglycerol phosphorylation. Metabolic crenation of erythrocytes coincides with the conversion of phosphatidylinositol-4,5-bisphosphate to phosphatidylinositol and of phosphatidic acid to diacylglycerol. Lipid dephosphorylation is reversed by the addition of sugars and accompanies the shape recovery.[12] The phosphorylation of these lipids was examined in DTT-induced stomatocytes. Cells were metabolically depleted in the presence of $^{32}P_i$. The resulting echinocytes were incubated with sugars in the presence and absence of DTT. The shape recovery to discocyte and the DTT-induced stomatocyte formation were both accompanied by an increase in the ^{32}P incorporated into phosphatidylinositol-4,5-bisphosphate, a decrease in phosphatidylinositol-4-phosphate levels and no change in the levels of phosphatidic acid (Fig 11). DTT had no effect on the amount of ^{32}P incorporated into phosphatidylinositol-4,5-bisphosphate, phosphatidylinositol-4-phosphate, phosphatidic acid, or any other phospholipid.

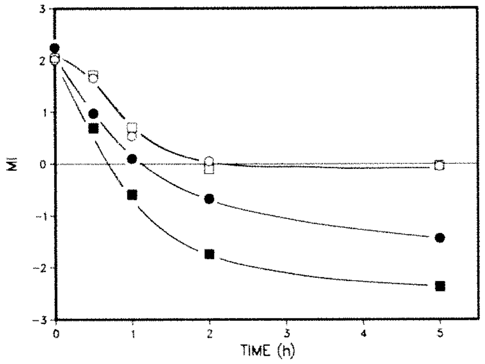

Fig 8. **Effect of TosPheCH$_2$Cl on DTT-induced stomatocytosis. Cells were metabolically crenated for 22 hours, treated with dimethyl sulfoxide (○, ●) or with TosPheCH$_2$Cl in dimethyl sulfoxide (□, ■), and then resuspended in supplemented NaCl/P_i without (○, □) or with 10 mmol/L DTT (●, ■).**

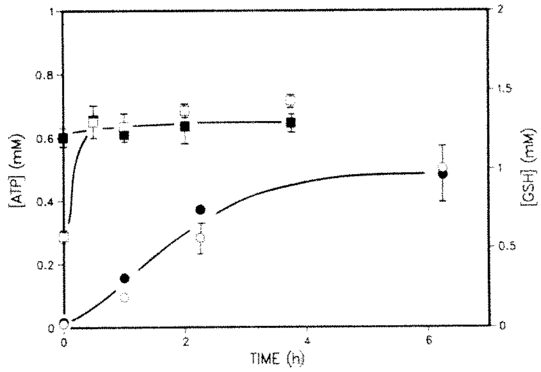

Fig 9. **ATP and glutathione levels during shape recovery. Data from two experiments are shown. Cells were metabolically depleted for 23 hours for GSH measurements (□, ■), or for 25 hours for ATP measurements (○, ●). Recovery was carried out in NaCl/P_i without (○, □) or with 10 mmol/L DTT (●, ■). Values are the average of two measurements. Error bars in this and all subsequent figures represent one standard error.**

DISCUSSION

The sulfhydryl reducing agent DTT has no evident effect on the morphology of normal human discocytes or echinocytes generated by metabolic depletion. However, when DTT is present during ATP repletion, echinocytes recover, not to discocytes, but to stomatocytes. The severity of the stomatocytosis is a function of the degree of initial crenation; more severely echinocytic cells cup more extensively. This is true both for cells depleted for varying lengths of time and for partially recovered echinocytes incubated in supplemented medium for varying lengths of time. Thus, DTT intervenes in some way in an ATP-dependent mechanism that restores and regulates cell shape.

Oxidative damage of cell components. The stability of ghosts and of cytoskeletal protein complexes depends on the integrity of sulfhydryl groups in actin and band 3.[23] Palek et al[14] found that DTT accelerates sugar-dependent shape recovery of metabolically depleted echinocytes.* They proposed that the cytoskeleton undergoes oxidative damage during depletion and that such damage must be repaired during repletion before the cell can assume its normal shape. These considerations raised the possibility that DTT affects cell shape by reducing certain protein sulfhydryl groups

---

*These authors do not report finding stomatocytes in the population of recovered cells. The discrepancy between their results and the present findings may be due to differences in experimental conditions or in the method of assigning cell morphology.

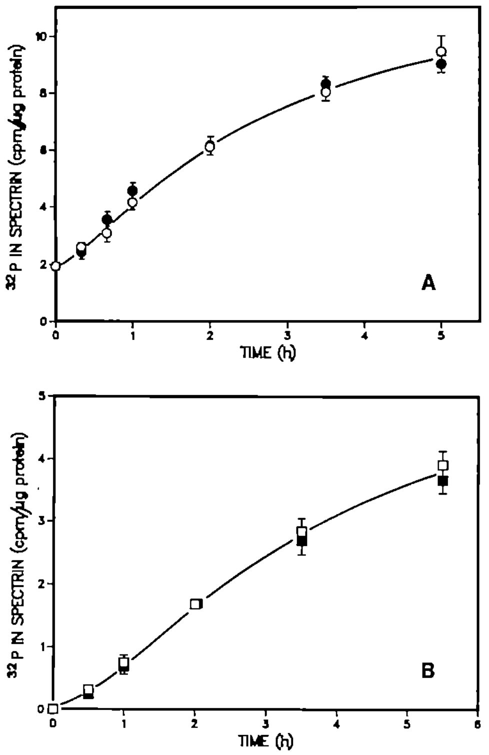

Fig 10. Spectrin phosphorylation and DTT-induced stomatocytosis. (A) Net phosphorylation in the band 2 region. Cells were pre-labeled with ^{32}P, metabolically depleted for 32 hours, pelleted and resuspended in sugar-supplemented ^{32}P-containing buffer with (●) or without 10 mmol/L DTT (○); $t_{1/2}$ of shape recovery – 1.5 hours. Values are the average of three measurements. (B) Rephosphorylation and turnover. Cells were depleted for 23 hours, pelleted, and resuspended in sugar-supplemented ^{32}P-containing buffer with (■) or without 10 mmol/L DTT (□); $t_{1/2}$ of shape recovery – two hours. Values are the average of four measurements.

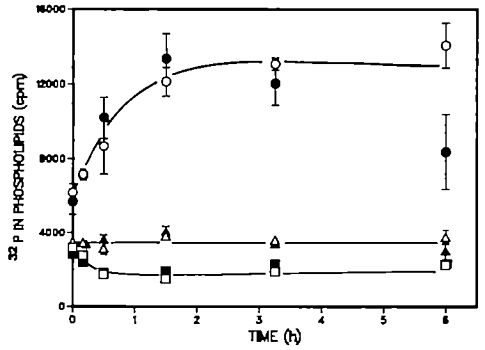

Fig 11. Phosphoinositide metabolism and DTT-induced stomatocytosis. Cells were metabolically depleted in ^{32}P-containing buffer for 21 hours and then diluted in sugar-supplemented buffer with or without 10 mmol/L DTT; $t_{1/2}$ of shape recovery – two hours. Phosphatidylinositol bisphosphate (○, ●), phosphatidylinositol monophosphate (□, ■), and phosphatidic acid (△, ▲). No differences in any lipid concentration were observed in the absence (○, □, △) or presence (●, ■, ▲) of 10 mmol/L DTT. Values are the average of four measurements.

beyond the extent normally attained in metabolic processes, releasing oxidative constraints to an abnormal degree. If the susceptibility of these proteins to such alteration were increased by the putative oxidative damage, the DTT effect might manifest itself, as observed, only in cells recovering from crenation.

This possibility was examined in experiments in which cells were allowed to crenate in the absence of oxygen or in the continuous presence of DTT. Neither of these treatments affects the degree of stomatocytosis observed when the echinocytes were supplemented with sugars and DTT. Alternatively, echinocytes generated under the usual experimental conditions were incubated for two hours with DTT and then supplemented with nutrients and allowed to change shape in the absence of DTT. These cells recover discocytic shape but do not become stomatocytic. Thus, protection of cells from oxidative damage does not abolish the effects of DTT.

Time course and concentration dependence of DTT responses. DTT must be present continuously not only for stomatocyte formation, but also for maintenance of the stomatocytic shape. When the reducing agent is removed, stomatocytes slowly revert to discocytes. This "relaxation" occurs on a longer time scale than the initial stomatocyte formation, indicating that the cell is slow to overcome the effects of DTT. The relaxation observed might be a reversal of the stomatocytic process, occurring at a slower rate because the cell's metabolic activity has reached a steady state; or it might involve a separate mechanism. It is perhaps significant that the time scale of stomatocyte reversal approaches the time scale of phospholipid flip-flop.[24]

DTT does not act in a stoichiometric fashion. Half-maximal stomatocytosis is observed at 2 to 3 mmol/L DTT, regardless of the initial degree of crenation or the cell concentration. This finding, together with the requirement for continuous presence of DTT, is more consistent with modulation of an enzyme activity than with direct reductive action on cytoskeletal protein structure.

Other reducing agents. Sulfhydryl reducing agents other than DTT induce stomatocyte formation in metabolically depleted echinocytes. Dithioerythritol effects stomatocytosis at the same concentration and to the same extent as does DTT. 2-Mercaptoethanol also induces stomatocyte formation but to a lesser extent, even at tenfold higher concentrations. The relative effects of mercaptoethanol and the bivalent reagents may reflect differences in their reduction potentials. The anomalous electrode behavior of thiols in aqueous solutions has made reliable determination of their relevant electrode potentials difficult, but relative values for mercaptoethanol and DTT may be inferred from their equilibrium constants for reduction of protein sulfhydryl groups: the value for mercaptoethanol is approximately unity, 10^4 less than that for DTT and dithioerythritol.[25]

Metabolic effects. ATP and glutathione are metabolic intermediates depleted during crenation and regenerated as cells return to discocytes. Neither process appears to be the target of DTT. The rate and extent of ATP resynthesis are not affected by DTT. Cells depleted under nitrogen retain higher levels of reduced glutathione than cells depleted in air, but DTT induces stomatocytosis in cells of both types at the same rate and to the same extent. DTT reduces oxidized glutathione within the first 20 minutes of incubation, but normal metabolic processes restore control cells to the same level well before stomatocytosis develops, and DTT does not alter the final level of reduced glutathione in the cell.

Protein phosphorylation. The rephosphorylation of spectrin, once thought to be the event effecting the echinocyte-to-discocyte transformation, is not altered during the echinocyte-to-stomatocyte transformation. DTT does not change the rate of spectrin rephosphorylation, nor does it alter phosphate turnover in band 2. No differences in phosphorylation of other membrane proteins are observed in DTT-treated and control cells.

Phosphoinositide metabolism and bilayer balance. The discocyte-to-echinocyte transformation in red cells is coupled to the metabolism of cell phosphoinositides.[12] During metabolic depletion, crenation coincides with the conversion of phosphatidylinositol-4,5-bisphosphate to phosphatidylinositol and phosphatidic acid to diacylglycerol. The reversal of the shape change by the addition of nutrients reverses this lipid dephosphorylation. Phosphoinositide phosphorylation is not responsible for DTT stomatocytosis; the rate of formation and equilibrium levels of phosphatidylinositol-4,5-bisphosphate and phosphatidic acid are indistinguishable in recovered discocytes and in DTT-induced stomatocytes. If the apparent connection between phosphoinositide phosphorylation and cell shape is due simply to steric effects on membrane bilayer balance, as suggested earlier,[12,13] the present findings would indicate that more than one metabolic mechanism influences cell shape. The morphology change from echinocyte to discocyte to stomatocyte has been viewed as a continuum, as in the case of amphipath intercalation. If metabolically mandated shape changes are also governed by a single biochemical mechanism, it is more complex than simple phosphoinositide occupancy of inner monolayer area.

From presently available evidence, DTT-induced stomatocytosis could be a bilayer effect, a cytoskeletal effect, or both. The time scale of the process is consistent with the rate of phosphatidylserine translocation across the bilayer.[16,26] Possibly, DTT activates a phospholipid translocation protein, causing net transfer of phospholipid to the inner monolayer. Alternatively, DTT may directly or indirectly alter cytoskeletal protein interactions, either among themselves or with the bilayer by way of the formation of a metabolite such as a polyanion.[7,27-29] Our preliminary results may support the last hypothesis. Conditions that elevate cell 2,3-diphosphoglycerate levels during shape recovery induce additional morphological anomalies, which are under further investigation.

Cells incubated with the amphipath dinitrophenol crenate, presumably due to the intercalation of dinitrophenol into the cell outer monolayer.[30] The echinocytes generated by this agent revert slowly to discocytes in the presence of glucose. This shape recovery is accelerated by TosPheCH$_2$Cl and hexose monophosphate shunt activators in normal cells,[22,31] an effect not found in glucose-6-phosphate-dehydrogenase–deficient cells. The shape recovery from dinitrophenol crenation may be related to DTT-induced stomatocytosis. TosPheCH$_2$Cl has no effect on the shape reversion of echinocytes to discocytes, but it potentiates the stomatocytic effect of DTT. This provides additional evidence that enzymes of the metabolic cycles are targets for the reducing agents.

Morphology control in ghosts. Under some conditions, ghosts resealed around physiological concentrations of MgATP form echinocytes that gradually become discoid and then stomatocytic.[6,7,32,33] These shape changes coincide with formation of phosphatidic acid,[34] and phosphatidylinositol-4,5-bisphosphate may also be elevated under some conditions.[35] The degree of stomatocytosis eventually attained in ghosts depends on the degree of washing they receive as well as the buffer and temperature used: greater stomatocytosis and endocytosis are observed with ghosts washed extensively before resealing (unpublished observations, 1984). It is possible that ghosts and DTT-treated echinocytes share the same biochemical lesion that prevents them from maintaining discoid shape.

Localization of Factor VIII-Procoagulant Antigen: An Immunohistological Survey of the Human Body Using Monoclonal Antibodies

By Theo H. v.d. Kwast, Herbert V. Stel, Ellen Cristen, Rogier M. Bertina, and Enno C.I. Veerman

Various organs, including liver, spleen, heart, lung, kidney, intestines, lymph nodes, pancreas, bone marrow, and thymus, were investigated for the presence of factor VIII-procoagulant antigen (VIIICAg) and factor VIII-related antigen (VIIIRAg), using a panel of monoclonal antibodies directed to factor VIII-von Willebrand factor in combination with a sensitive immunoperoxidase staining technique. In addition to hepatic sinusoidal endothelial cells, the presence of VIIICAg was demonstrated in mononuclear cells sporadically present in lymph nodes, in the alveolar septa of lung, and in the red pulp of spleen. The identity of these mononuclear cells could not be unequivocally determined. Based on morphological criteria, however, it is tentatively concluded that these cells are nonlymphoid and belong to the mononuclear phagocyte system. The presence of VIIIRAg was confined to vascular endothelial cells, hepatic sinusoidal endothelial cells, cells lining the venous sinuses of the red pulp of the spleen, cells lining renal glomeruli and lung capillaries, platelets, and megakaryocytes.

FACTOR VIII-von Willebrand factor (FVIII-vWF), a high-molecular-weight glycoprotein complex that has an important role in hemostasis, consists of two discernible components. These are factor VIII, the procoagulant component absent in severe hemophilia A, and von Willebrand factor (vWF), the component that is absent in severe von Willebrand's disease.[1] Immunohistological[2] and recombinant DNA studies[3-5] have indicated that factor VIII is present in and synthesized by liver cells. From earlier transplantation and perfusion studies,[6-8] circumstantial evidence was obtained that the liver is involved in the synthesis of factor VIII; however, a variety of other organs have been implicated in the synthesis of factor VIII as well.[9-11] Hence the possibility of extrahepatic synthesis of factor VIII cannot be excluded in advance. This prompted us to extend the immunohistological search for VIIICAg to various other organs and cell types by use of a panel of monoclonal antibodies with different specificity to factor VIII. In addition, parallel experiments were performed using monoclonal antibodies against vWF.

It appeared that the presence of factor VIII was restricted to two cell types: hepatic sinusoidal endothelial cells and mononuclear cells, found sporadically but consistently in lung, spleen, and lymph nodes.

MATERIALS AND METHODS

Monoclonal antibodies. For this study eight monoclonal antibodies to factor VIII and four monoclonal antibodies to vWF were used. Description of techniques for characterization of these antibodies have been provided elsewhere and are applicable for this study.[2,12] Some of these antibodies have already been described in detail elsewhere.[2,13-16] In brief, monoclonal antibodies CLB-CAg A (IgG_{2a}), CLB-CAg 21 (IgG_{2a}), CLB-CAg 44 (IgG_{2a}), CLB-CAg 58 (IgG_{2a}), CLB-CAg 61 (IgG_1), CLB-CAg 78 (IgG_1), CLB-CAg 117 (IgG_{2a}), and C 6 (IgG_1, IgG_{2b}) are directed to factor VIII as judged by the following criteria: they bind to purified FVIII-vWF[17] and to FVIII-vWF present in normal plasma, but they do not react with severe hemophilia A plasma (negative for material cross-reacting with a human antibody to VIIICAg). Some of these antibodies inhibit factor VIII-procoagulant activity (VIIIC): C6 (5,000 Bethesda units (BU)/mg IgG), CLB-CAg A (150 BU/mg IgG), CLB-CAg 58 (5 BU/mg IgG), and CLB-CAg 117 (2 BU/mg IgG), whereas the other monoclonal antibodies do not inhibit VIIIC. All these monoclonal antibodies react with serum VIIICAg, exept antibody C6, which suggests that the C6 antibody is specific for the native conformation of the factor VIII molecule. As deduced from the results of competitive displacement studies carried out essentially as described by Stel et al,[15] these antibodies were directed to different epitopes on factor VIII. Monoclonal antibodies CLB-RAg 1 (IgG_1), CLB-RAg 7 (IgG_1), CLB-RAg 35 (IgG_{2a}), and CLB-RAg 50 (IgG_1) are directed to vWF[15,16]: they bind to purified FVIII-vWF, to FVIII-vWF present in normal plasma, and to FVIII-vWF present in severe hemophilia A plasma. In contrast, these antibodies do not react with plasmas of patients with severe von Willebrand's disease (negative for material cross-reacting with a rabbit antibody to vWF). Competitive displacement studies showed that these antibodies are directed to different epitopes on vWF.

Immunoperoxidase staining procedure. A sensitive multistep immunoperoxidase staining method was used to demonstrate the presence of VIIICAg. This procedure has been described in detail by Lansdorp et al.[18] Sheep antimouse immunoglobulin (SAM) (Central Laboratory of the Netherlands Red Cross Blood Transfusion Service [CLB], Amsterdam) was used to link peroxidase-mouse monoclonal antiperoxidase complexes (PAP) (CLB) to the initial monoclonal antibody (eg, monoclonal antibody to VIIICAg). The multistep PAP procedure was based on repeated subsequent incubation cycles with SAM and PAP complexes, respectively. The experimental details of the immunostaining procedure were as follows: (1) cryostat sections of 5-μ thickness were air-dried, fixed in acetone for ten minutes, and washed in phosphate-buffered saline (PBS) for ten minutes; (2) monoclonal antibodies (undiluted culture supernatant or ascitic fluid diluted 1:400 to 1:1,000 in PBS-gelatine 0.2%) were overlaid on the tissue and allowed to incubate for two hours at room temperature; (3) SAM, diluted 1:100 in 0.1 mol/L Tris-HCl (pH 7.5) containing 10% normal human serum and 10% normal sheep serum, was applied to the slides. Incubation was allowed for 30 minutes at room temperature; (4) PAP complexes, diluted 1:100 in the above-mentioned Tris-HCl buffer containing 10% normal sheep serum and 10% normal human serum, were overlaid on the tissue for 30 minutes. Between steps 2, 3, 4, and 5, the sections were washed in PBS for five minutes. To improve the sensitivity of the immunoperoxidase staining procedure, steps 3 and 4 were repeated twice before (5) peroxidase activity was detected using the substrate 3-3'-diaminobenzidine (DAB) (Sigma Chemical Co, St Louis) (1

mg DAB/mL in PBS containing 0.01% hydrogen peroxidase). After five to ten minutes' incubation in the dark, the sections were washed in PBS, dehydrated, and mounted with Malinol (Chroma, Stuttgart, FRG). Similar immunostaining results were obtained when, in steps 3 and 4 of the immunostaining procedure, normal serum was substituted by serum obtained from a patient with severe von Willebrand's disease. The possibility that all immunostaining results obtained with the monoclonal antibodies to FVIII-vWF were due to Fc-binding of these antibodies to the stained cells was excluded by the absence of reactivity with monoclonal antibodies directed to unrelated antigens of the same immunoglobulin subclasses and by the finding that saturation of Fc receptors by preincubation with aggregated gamma globulins[19] had no effect on the immunostaining results obtained with the monoclonal antibodies to FVIII-vWF. The monoclonal antibodies to unrelated antigens used were a monoclonal antibody directed to T lymphocytes (IgG_{2a}) (Becton Dickinson, Antwerp, Belgium), to mouse thymocytes (IgG_{2a}) (kindly provided by Dr W.v. Ewijk, Erasmus University, Rotterdam, The Netherlands), to trinitrophenyl (IgG_1), to house dust mite (IgG_1), and to cat allergen (IgG_1). The latter three monoclonal antibodies were kindly provided by Dr R.C. Aalberse, CLB, Amsterdam, The Netherlands.

Tissues. Tissues (pancreas, intestines, liver, kidney, lymph node, lung, heart, thymus, vena cava, and aorta) were collected at autopsies on patients deceased less than three hours. Tissue that showed no abnormality was selected for immunohistological study. Tissue of liver, kidney, and lymph node were also obtained through biopsy. Spleens were obtained from patients during surgery. Small tissue blocks were quick frozen and stored in liquid nitrogen. Bone marrow was aspirated by sternum punction, and cytocentrifuge smears were made before immunoperoxidase staining.

Cultured endothelial cells. Endothelial cells isolated from human umbilical veins were cultured[20] until confluent monolayers were obtained. After removal of culture medium and washing with PBS, the endothelial cells were incubated with RPMI 1640 (GIBCO, Biocult, UK) supplemented with 1% (wt/vol) human serum albumin. After 48 hours' incubation, samples were taken from the supernatant medium and stored at −70 °C until assayed for VIIICAg and VIIIRAg. For immunohistological studies, endothelial cells were cultured on glass coverslips until confluency was reached. After several washes with PBS to remove traces serum, cells were fixed in acetone for ten minutes and washed with PBS before immunoperoxidase staining.

Determination of VIIICAg and VIIIRAg. VIIICAg was measured using an immunoradiometric assay relying on Sepharose-linked monoclonal antibodies and human antibodies to VIIICAg.[13,14] The lower limit of detection with this assay is 0.0005 units of VIIICAg per milliliter. Determination of VIIIRAg was essentially as described by Ruggeri et al.[21] One unit of VIIICAg and VIIIRAg is the amount of antigen present in 1 mL of pooled normal plasma.

RESULTS

Localization of factor VIII (VIIICAg) in liver tissue. The localization of VIIICAg in liver biopsy material from 20 patients with mild or no detectable liver disease was investigated with an immunoperoxidase staining procedure using eight monoclonal antibodies directed against different epitopes on factor VIII. With each of these monoclonal antibodies, the most consistent finding was labeling of the cells lining the hepatic sinusoidal spaces (Figs 1 and 2). Diffuse as well as granular deposition of the immunoperoxidase reaction product could be observed in the cytoplasm of these cells (Fig 3). Hepatic parenchymal cells, as well as the vascular endothelial cells lining hepatic arteries and veins, were negative. No subendothelial deposition of immunoreactive material around arteries and veins was observed. Similarly, when liver tissue obtained from five patients with severe hepatic parenchymal disease (severe cirrhosis) was tested with these antibodies, it appeared that the cells lining the liver sinusoids were positive (results not shown). The observed immunostaining patterns obtained with these eight anti-VIIICAg monoclonal antibodies were similar, and only slight differences in staining intensity were occasionally present. Labeling of the sinusoidal liver cells could only be demonstrated by repeating the incubation cycles in the immunostaining procedure (see Materials and Methods). Apparently, one single incubation cycle in the immunostaining procedure was not sufficient to visualize the immunoreactive material present in these cells; therefore, in all subse-

quent experiments, we used the multistep immunostaining procedure.

In control experiments, monoclonal antibodies directed to unrelated antigens of the same subclasses as the monoclonal antibodies to VIIICAg tested were negative (Fig 4).

Localization of vWF (VIIIRAg) in liver tissue. When monoclonal antibodies to VIIIRAg were tested on liver biopsy material from 25 patients with absent, mild, or severe hepatic disease, deposition of the immunoperoxidase reaction product, both diffuse and granular, was present in the endothelial cells lining hepatic arteries and veins, as well as in the sinusoidal liver cells (Fig 5). Subendothelial deposition of immunoreactive material was noted around hepatic arteries and veins. The sinusoidal staining pattern obtained with these anti-VIIIRAg antibodies was similar to that obtained with the anti-VIIICAg antibodies (compare Figs 1 and 5). As in the case of VIIICAg, the presence of VIIIRAg in the sinusoidal liver cells could only be consistently demonstrated after repetition of the incubation cycles in the immunostaining procedure. In contrast, the presence of VIIIRAg in vascular endothelial cells was readily detectable after only one cycle of immunostaining. The most likely explanation is that this reflects differences in the amount of antigen present in these cells.

Identification of Kupffer cells in liver sinusoids. An antibody directed to lysozyme (Dako, Glostrup, Denmark) was used to identify the Kupffer cells present in the liver sinusoids. As shown in Fig 6, the Kupffer cells represent a minority of the sinusoidal liver cell population, most of these cells being sinusoidal endothelial cells.[22,23]

Localization of factor VIII and vWF in other organs. Vascular endothelial cells present in other organs (lung, spleen, lymph nodes, pancreas, intestines, heart, thymus) and the endothelial cells lining the larger blood vessels (aorta, vena cava, endocard) did not stain with any of the monoclonal antibodies to VIIICAg tested. Occasionally, a faint, scattered staining in the glomerulus of the kidney was observed; however, we were not able to confirm this unequivocally despite the recent detection of factor VIII-mRNA in renal tissue.[24] No VIIICAg could be detected in the sinusoidal endothelial cells lining the venous sinuses in the red pulp of the spleen; however, immunostaining was noticed in mononuclear cells sporadically present in the red pulp of the spleen (Fig 7), the alveolar septa of the lungs (not shown), and in lymph nodes (Fig 8). These cells, consistently found in these tissues, were stained by all eight monoclonal antibodies to VIIICAg. It appeared that the immunostaining was weak and diffuse, in contrast with the observed immunostaining in the cells lining the liver sinusoids. As deduced from the relatively large cell size and small nucleus/cytoplasm ratio, these mononuclear cells are presumably nonlymphoid and part of the mononuclear phagocyte system (probably macrophages).[25]

Positive immunostaining for VIIIRAg was present in the cytoplasm of endothelial cells lining large and small arteries, veins, and capillaries. The endothelial cells lining the renal glomeruli and lung capillaries and the cells lining the venous sinuses in the spleen were also positive (Fig 9). Staining was both diffuse and granular, and this specific staining was achieved with all four of the tested monoclonal antibodies to VIIIRAg. Subendothelial deposition of VIIIRAg could only be discerned in arteries, arterioles, and larger veins. The multistep immunostaining procedure was essential to obtain consistent positive results for the cells lining the venous sinuses in the spleen and for the glomerular endothelial cells present in the kidney. By contrast, neither in the cells lining the lymphatic vessels nor in the cells lining the lymph node sinuses could VIIIRAg be demonstrated. In addition, repeated testing with the anti-VIIIRAg antibodies of lung, lymph node, and spleen tissue failed to reveal staining for VIIIRAg in mononuclear cells present in these tissues.

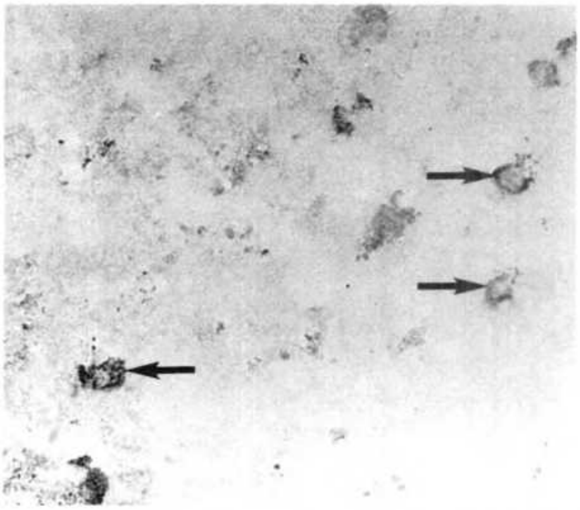

Fig 8. **Section of lymph node (paracortical area) stained with anti-VIIICAg monoclonal antibody C6. Note the labeling of mononuclear cells (arrow). (Original magnification ×125; current magnification ×112; multistep immunostaining procedure.)**

Bone marrow. None of the monoclonal antibodies to VIIICAg reacted with cells present in bone marrow. Megakaryocytes and platelets, however, showed immunostaining with all monoclonal antibodies to VIIIRAg that were tested (results not shown).

Cultured endothelial cells. The immunostaining experiments were repeated on cultured endothelial cells derived from human umbilical veins. In contrast with the monoclonal antibodies to VIIIRAg, which showed a diffuse and granular staining, the monoclonal antibodies to VIIICAg did not react with these cells. In addition, with immunoradiometric assays[13,14] capable of detecting an amount of (serum) VIIICAg as low as 0.0005 U/mL, no VIIICAg could be demonstrated in the culture supernatant, although amounts of

VIIIRAg were readily detectable (25 mU VIIIRAg/10^5 endothelial cells per 48 hours).

DISCUSSION

Using a sensitive immunostaining technique and monoclonal antibodies with different specificity against FVIII-vWF, several organs from the human body have been screened for the presence of factor VIII and vWF. The presence of material immunoreactive with anti-VIIICAg monoclonal antibodies, and hence representing VIIICAg, could be demonstrated in at least two cell types: (1) in cells lining the hepatic sinusoidal spaces, thus confirming results reported previously with only one monoclonal antibody to VIIICAg,[2] and (2) in mononuclear nonlymphoid cells occurring sporadically in lung, spleen, and lymph nodes. The latter results are corroborated by the work of Exner et al,[26] who reported a relatively high concentration of VIIICAg in lymph nodes and lung. Of those cells that were positive for factor VIII, the liver sinusoidal cells contained both VIIICAg and VIIIRAg, whereas in the mononuclear cells, only VIIICAg seemed to be present. The identity of the latter cells could not be unequivocally determined. Judging by morphological criteria (size of cell and nucleus), we tentatively propose a subset of macrophages as the most likely candidate. With regard to the identity of the VIIICAg containing liver sinusoidal cells, both Kupffer cells and sinusoidal cells can be considered as candidates. In view of the differences in staining patterns obtained with anti-VIIICAg antibodies (Fig 2) and with antilysozyme antibodies (Fig 6) (the latter being a marker for Kupffer cells), it seems likely that the presence of VIIICAg in liver is not restricted to Kupffer cells. The staining pattern obtained with the anti-VIIICAg and anti-VIIIRAg antibodies is more characteristic for hepatic sinusoidal endothelial cells, which outnumber the more patchily distributed Kupffer cells in the liver sinusoids.[23] Although the involvement of Kupffer cells cannot be excluded, the hepatic sinusoidal endothelial cells are the most likely candidates to contain both VIIICAg and VIIIRAg. In the case of VIIIRAg, this view is supported by data reported by Soda and Tavassoli.[27] Using an indirect immunofluorescence technique in combination with a polyclonal rabbit anti-vWF serum, they showed that in liver suspension of rat Kupffer cells and sinusoidal endothelial cells, only the sinusoidal endothelial cells contained VIIIRAg.

Based on the combined results of the present immunohistological study and previous recombinant DNA studies,[3-5] we favor the concept that hepatic sinusoidal endothelial cells provide a site of synthesis for factor VIII.

The possibility that factor VIII is synthesized by hepatic parenchymal cells[28] and, subsequently, stored in sinusoidal endothelial cells seems unlikely to us, since patients in the terminal stage of hepatic parenchymal disease have normal or elevated levels of factor VIII and reduced levels of vitamin K-dependent clotting factors,[29,30] the latter known to be synthesized by liver parenchymal cells.[7] The results of the present study, which show no deviate sinusoidal immunostaining with anti-VIIICAg antibodies in patients with severe hepatic parenchymal disease, are consistent with these findings.

The significance of the presence of factor VIII in mononuclear cells (probably macrophages) occurring in spleen, lung, and lymph nodes is unclear. Macrophages, with their strong phagocytic and degrading capacities, are potential sites of clearance of factor VIII. On the other hand, macrophages have been frequently reported to actively synthesize a remarkable variety of substances,[31] including clotting factors.[32-35] In this respect, it is interesting to note that these mononuclear cells reacted with anti-factor VIII monoclonal antibody C6, which does not react with serum (degraded) VIIICAg. Although this indicates that at least part of the factor VIII molecules are present in their native form, the possibility of uptake of native factor VIII cannot be ruled out. It will be clear that the issue synthesis *v* absorption cannot be resolved with immunohistological studies alone.

Lymphokine Induction of NK-Like Cytotoxicity in T Cells From B-CLL

By Melchor Alvarez de Mon, Juan Casas, Rafael Laguna, María Luisa Toribio,
Manuel O. de Landázuri, and Alberto Durántez

T cells from patients with B cell chronic lymphocytic leukemia (B-CLL) exhibit defective natural killer (NK) activity. In this study, we have analyzed the cytotoxic-inducer effects of gamma interferon (γ-IFN) and supernatants containing interleukin 2 (IL 2 sup). T cells from patients with B-CLL were incubated with γ-IFN or IL 2 sup. γ-IFN did not modulate the very low or undetectable levels of NK activity present in the T cell population. However, the IL 2 sup induced a potent cellular cytotoxicity against NK-sensitive and NK-resistant tumoral target cells. This cytotoxic inducer effect (a) was present in lectin-free IL 2 sup and in a 15,000- to 20,000-dalton molecular weight fraction obtained by gel filtration chromatography of this supernatant; (b) was directed against NK-sensitive and NK-resistant target cells; (c) was not correlated with the basal levels of NK activity; and (d) was not associated with a development or augmentation of the proportion of lymphocytes with classic NK cell phenotype. Taken together, these results demonstrate that unstimulated T cells from B-CLL patients, incubated briefly (18 hours) with IL 2 sup but not γ-IFN, have strong NK-like cytotoxicity, despite the lack of classic NK activity.

© 1986 by Grune & Stratton, Inc.

B CELL CHRONIC lymphocytic leukemia (B-CLL) is characterized by the monoclonal expansion and accumulation of B cells, which are arrested in their differentiation pathway at an early stage.[1] There are indications that not only B cells are affected in B-CLL, but that T cells from these patients also show functional and phenotypic abnormalities.[2,3] In addition, it has been shown that E rosette-positive cells from B-CLL patients mediate defective natural killer (NK) cytotoxicity and antibody-dependent cellular cytotoxicity.[4,5] The defective NK activity present in these patients may play a role in the development of this disease, since NK activity is thought to be involved in the surveillance against tumors and in the control of both normal hematopoiesis and viral infection.[6,7]

It has been demonstrated that classic NK cells, defined by their ability to lyse a number of tumor cell line targets without prior activation, are modulated by interferon (IFN) and interleukin 2 (IL 2).[8,9] There are also reports describing the induction of killer cells[10,11] that lyse tumor cell line targets during long-term culture with lymphokine-conditioned medium. This study examined the in vitro effect of IL 2 supernatants (IL 2 sup) on T cells from B-CLL patients in the induction of cytotoxic activity against tumor target cells. Our results demonstrate that short-term (18 hours) incubation with IL 2 sup can induce strong NK-like activity in unstimulated T cells from B-CLL patients that lack classical NK activity.

MATERIALS AND METHODS

Patient population. Twenty-six previously untreated patients with clinically, histologically, and immunologically defined B-CLL (according to the Chronic Leukemia Myeloma Task Force 1973)[12] were studied. Their median age was 68 ± 9. Controls were 14 healthy, age- and sex-matched individuals.

Culture medium. RPMI 1640 (Microbiological Assoc, Walkersville, Md) supplemented with 1% L-glutamine (Flow Lab, Irvine, UK), 0.5% HEPES (Flow Lab), and 1% penicillin streptomycin (Difco Lab, Detroit) was used for cultures. This will be referred to as complete medium.

Isolation of lymphoid cells. Peripheral blood mononuclear cells (PBMs) were obtained from the heparinized venous blood of the subjects by Ficoll-Hypaque gradient centrifugation. T lymphocytes were separated by their capacity to form stable rosettes with neuraminidase-treated sheep red blood cells (SRBCs). Briefly, E-SRBCs (T cells) were obtained after incubation of PBMs with neuraminidase-treated SRBCs for two hours at 4 °C and centrifugation on a Ficoll-Hypaque gradient. The interphase, containing mainly B cells, null cells, and macrophages, is referred to as non-T cells. A T cell purity of 90% to 94% (51% ± 6% OKT4$^+$, 41% ± 10% OKT8$^+$) in the control group and 78% to 94% (36% ± 5% OKT4$^+$, 34% ± 4% OKT8$^+$) in the B-CLL group was obtained after subjecting pellets to hypotonic lysis in order to eliminate SRBCs.

Production of IL 2 supernatants. IL 2 sups were obtained from human tonsil lymphocytes stimulated with 1% phytohemagglutinin (PHA) (Difco Lab) for 24 hours, as previously described.[13] The culture supernatants were concentrated by double-step precipitation with $(NH_4)_2SO_4$ and dialyzed against phosphate-buffered saline (PBS), pH 7.4. The remaining PHA was removed by chicken red blood cell absorption, as reported elsewhere.[14] Partially purified IL 2 was obtained by gel filtration chromatography.[15] The IL 2 activity was recovered in fractions corresponding to a molecular weight (mol wt) of 15,000 to 20,000 daltons.

IL 2 was also obtained from a tumor T cell line. The Gibbon lymphosarcoma cell line, MLA-144, provided by Dr H. Rabin (Frederick Cancer Research Center, Frederick, Md), spontaneously releases a factor that is biologically and biochemically similar to human IL 2.[16] MLA-144 cells were cultured at 2 × 10^6 cells per milliliter in complete medium without serum for 48 hours. After the culture period, supernatants were collected and concentrated as previously described.

To study the production of IL 2 by the T cells from either patients or controls, 5 × 10^6 cells from each subject and control were resuspended in 1 mL of complete medium supplemented with 1% fetal bovine serum (FBS) and cultured for 24 h in the presence of 1% PHA in round-bottom culture tubes (Falcon, Oxnard, Calif). At the end of the culture period, the supernatants were collected and stored at −20 °C until tested. IL 2 assays were performed as previously described.[17]

PHA-stimulated cultures. Purified T cells were cultured in 200 μL of complete medium with 10% FBS and 1% PHA, at a density of

1.5 × 10^5 cells per well, in triplicates in 96-well plates (Dynatech, Billingshurst, UK) for three days. Plates were incubated at 37 °C in a 5% CO_2 humid atmosphere. On day 2, 1 μ Ci of [^{3}H]-thymidine was added, and 24 hours later, cultures were harvested (Skatron, A.S., Lyerbyen, Norway) and counted in a liquid scintillation counter.

Cell cultures with IL 2 sup. Cell cultures were set up in macrowells (1.6 × 10^6 cells per milliliter) in complete medium supplemented with 10% FBS and in the presence or absence of different concentrations of IL 2 sup. The cultures were carried out for variable periods.

Cells cultured with γ-IFN. As previously described, effector cell populations were cultured in macrowells (1.6 × 10^6 cells per milliliter) in complete medium supplemented with 10% FBS for 18 hours. In the last two hours, we added 1,000 IU/mL of human γ-IFN (specific activity 2 × 10^7 IU/mg protein HEM) (Research Inc, Rockville, Md).

Cytotoxicity assays. Cytotoxicity was quantified by a ^{51}Cr-specific release assay using the following tumor target cells: K-562, Chang, MT-1, Alab, Raji, Molt-4, Molt-4-Thioguanin resistant, and Jurkat. Assays were performed at effector-target ratios of 50, 25, and 12:1 in 96-microwell, round-bottom plates. After a four-incubation, 100 μL of supernatant from each well was collected and analyzed in a gamma counter. The specific lysis (SL) and lytic units (LU) were calculated as previously described.[18]

Cell surface markers. Indirect immunofluorescence (IIF) with the monoclonal antibodies (OKT4, OKT8 [Ortho, Raritan, NJ], and Leu 11b [Becton Dickinson, Mountain View, Calif] was performed as described.[19] Samples were prepared as described for IIF[19] and analyzed with an EPICS-C Flow Cytometer (Coulter Electronics, Hialeah, Fla).

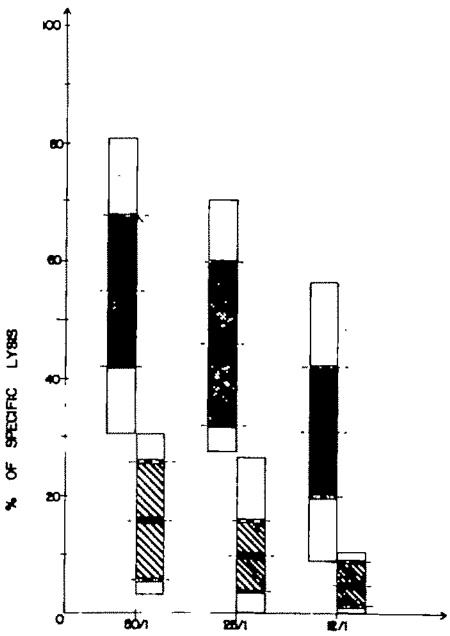

Fig 1. NK activity of T cells from B-CLL patients and normal controls at different effector-target cell ratio. The thick horizontal segments represent the geometric medium of each population. The shaded areas represent two standard deviations of the mean of each population. The extremes of the rectangles represent the rank of distribution of the data for each population. K-562 cells were used as target cells. ▨, Controls; ▨, B-CLL.

RESULTS

NK activity of PBMs, T, and non-T cells. PBMs, T, and non-T cells from 26 patients with untreated B-CLL and from 13 normal controls were separated to study their NK activity. As can be observed in Fig 1, E rosette-positive cells from B-CLL showed a significantly depressed NK activity when compared with normal controls ($P < .0001$, Mann-Whitney U test). Neither PBMs nor non-T cells from B-CLL mediated any significant cytotoxic activity (data not shown). The lack of NK activity present in the T cell-enriched population was not due to inhibition by the small number of contaminating non-T cells (range, 6% to 22%), since we observed in mixing experiments that non-T cells from B-CLL patients did not inhibit the cytotoxic activity of normal T cells (data not shown).

Modulation of the cytotoxic activity against K-562 target cells by γ-IFN and IL 2 sup. In preliminary experiments, we investigated whether IL 2 sup could induce cytotoxic activity in T cells from B-CLL patients. To this end, the T cells were incubated for two or 18 hours with IL 2 sup, and subsequently, their cytotoxic activity was tested against K-562 target cells. This revealed an increase in their lytic capacity that was maximal after incubation for 18 hours (lytic units at time 0 < 4 LU × 10^{-6} cells; after two hours – 20 LU × 10^{-6}; and after 18 hours, 40 LU × 10^{-6}). Therefore, in the following experiments, this period of incubation was routinely used.

To compare the cytotoxic-inducer effect of IL 2 with respect to γ-IFN, T cells from 12 cases of B-CLL with very low or absent levels of NK activity and T cells from controls with normal NK activity were incubated for 18 hours with these lymphokines (Table 1). After incubation with 1,000 IU/mL of γ-IFN, there was a significant increase in the cytotoxic activity of T cells in all the normal controls ($P < .05$, Wilcoxon signed-ranked test). In contrast, T cells from B-CLL patients were either unresponsive to γ-IFN (patients I, II, IV, and VI) or minimally so (rest of the patients). When the data of all 12 patients were analyzed together, the increments observed in NK activity after γ-IFN treatment were not statistically significant ($P > .05$, Wilcoxon signed-ranked test). On the other hand, when all the data from either patients or controls were examined, we did observe a significant correlation ($P < .05$, least squares method) between the levels of cytotoxicity observed after γ-IFN treatment and the basal values of NK activity (Fig 2).

The incubation with IL 2 sup of T cell from each of the B-CLL patients induced a significant increase in their ability to lyse K-562 target cells, which proved significant when all the cases were analyzed together ($P < .01$, Wilcoxon signed-ranked test). We also observed that the highest levels of cytotoxicity induced by IL 2 sup were obtained precisely in those patients who did not show spontaneous cytotoxic activity and did not respond to γ-IFN. We did not observe any correlation, either in B-CLL patients or in normal controls, between the basal levels of NK activity and the killing activity after incubation with IL 2 sup (Fig 2).

Table 1. Effects of γ-IFN and IL 2 Sup on Cytotoxic Activity of T Cells From B-CLL Against K-562 Target Cells

T cells from 12 B-CLL patients and six normal controls were incubated for 18 hours either with complete medium; complete medium for the first 16 hours, γ-IFN (1,000 IU/mL) being added in the last two hours; or complete medium plus 20% IL 2 sup. After this period of time, the cultures were analyzed for cytotoxic activity against K-562 target cells. The data are given as the percentage of specific lysis at effector-target cell ratios of 50:1, 25:1, and 12:1.

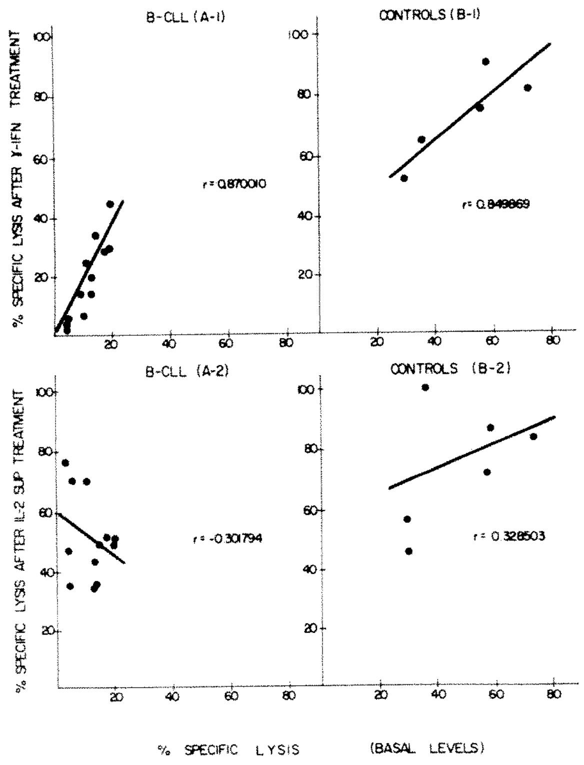

Fig 2. Correlations between the basal levels of cytotoxicity and (A) the lytic activity of T cells from B-CLL after incubation with γ-IFN (A-1) or IL 2 sup (A-2) and (B) the lytic activity of T cells from controls after incubation with γ-IFN (B-1) of IL 2 sup (B-2). The cytotoxic activity is expressed as a percentage of specific lysis against K-562 target cells at an effector-target cell ratio of 50:1.

This finding led us to study the possibility that the T cells from B-CLL patients could be deficient in their synthesis of IL 2. We found that IL 2 production by PHA-stimulated T cells from nine patients were similar to that of six normal controls (Fig 3). However, the proliferative response to PHA stimulation of the T cells from these B-CLL patients

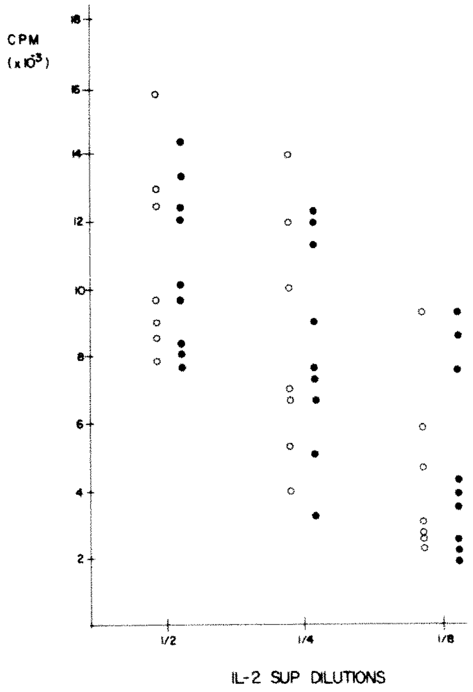

Fig 3. Proliferative response of long-term cultured human T cells after a 36-hour incubation period, in culture, with different proportions of IL 2 sup produced by T cells from either B-CLL patients (●) or normal controls (○).

(34,407 ± 15,709 cpm/1.5 × 10^5 cells) was significantly decreased ($P < .01$, Mann-Whitney U test) when compared with that of the normal controls (87,082 ± 21,179 cpm/1.5 × 10^5 cells).

We also ruled out the possibility that the enhancement of cytotoxic activity by IL 2 sup was due to activation of the contaminating non-T cells, since we did not observe any cytotoxic activity when non-T cells from B-CLL patients were incubated with IL 2 sup (data not shown). To investigate whether the observed effects were due to PHA that could still be present in the IL 2 sup, we used supernatants from the T cell line, MLA-144, which have been shown to produce IL 2 constitutively. As can be seen in one representative experiment (Fig 4), MLA-144 sup induced an increase in the cytotoxic activity of T cells from B-CLL patients similar to that of IL 2 sup. Finally, and to further delineate the molecules responsible for the enhancement of the cytotoxic activity, we used a semipurified preparation of IL 2 obtained by gel filtration chromatography (15,000 to 20,000 mol wt). As can be seen in Fig 4, this preparation also induced strong cytotoxic activity in T cells from B-CLL patients.

We investigated the target cell specificity of the T cells from B-CLL patients after incubation with IL 2 sup. As can be seen in Fig 5, short-term incubation with IL 2 sup induced lytic activity against both NK-sensitive and NK-resistant target cells.

Finally, since the previous results demonstrated that IL 2 sup induced strong NK-like activity in the T cells from B-CLL patients, we studied whether this cytotoxic-inducer effect could be explained by an increase in the percentage of lymphocytes with the classic NK cell phenotype. In five experiments we observed that incubation of the IL 2 sup did not modify the low percentage of Leu 11^+ cells (<1%) present in the T-enriched populations from the B-CLL patients.

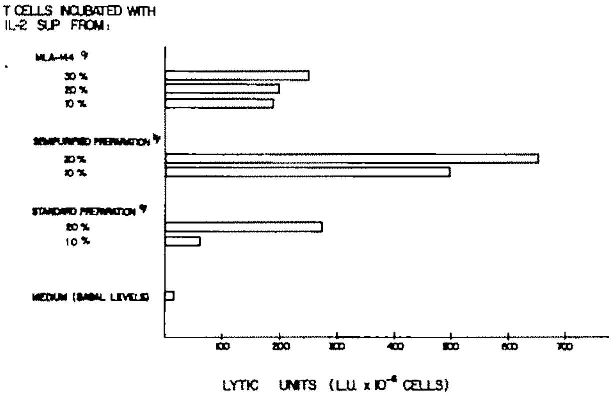

Fig 4. Cytotoxic activity of T cells from B-CLL patients after treatment with different IL 2 preparations. T cells were incubated either with complete medium (basal levels) or with the indicated concentrations of IL 2 from the T cell line MLA-144 (a), from a semipurified preparation obtained by gel chromatography (mol wt 15,000 to 20,000 daltons) (b), or from a standard preparation (c). After 18 hours of treatment, the cultures were analyzed for cytotoxic activity against K-562 target cells. The data are given in lytic units, LU 10^{-6} cells, as described in the text.

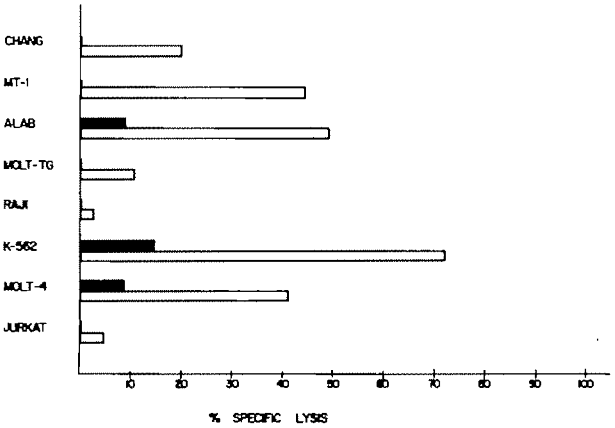

Fig 5. Cytotoxic activity of T cells from B-CLL against different target cells. T cells were incubated with either complete medium (□, closed bars) or 20% IL 2 sup (□, open bars). After 18 hours of treatment, the cultures were analyzed for cytotoxic activity against Chang, MT-1, Alab, Molt-TG, Raji, K-562, Molt-4, and Jurkat target cells. The data are given in percentage of specific lysis at an effector-target cell ratio of 50:1.

DISCUSSION

This paper, above all, poses an intriguing question regarding the nature of the IL 2 sup-induced cytotoxicity generated in the T cells obtained from untreated B-CLL patients. The origin of these effector cells may be explained by (a) the activation of already mature NK cytotoxic cells; (b) the differentiation of pre-killer NK cells into effective cytotoxic cells; or (c) the recruitment of a different cell population not related to the NK pathway. Our data suggest that this last possibility is the most likely. The following reasons support this contention. First, there was no correlation between the basal levels of NK activity and the cytotoxicity acquired after incubation with IL 2 sup. Second, mature NK cells responded to IFN with an increment in their lytic activity, but using T cells from B-CLL patients, we did not observe this enhancement. (Other authors have also reported this observation.[4,5]) Third, the cytotoxicity generated by the IL 2 sup was active against both NK-sensitive and NK-resistant target cells. Finally, there was no induction of cytotoxic effector lymphocytes with phenotype of classic NK cells after the incubation with IL 2 sup.

Furthermore, recent reports in the literature support the possibility that, in some systems, the effector cells generated by IL 2 are not typical mature NK cells. We have observed that human thymocytes cultivated in the presence of IL 2 sup acquire de novo cytotoxic activity against tumor target cells.[15] Grimm et al[10] showed that PBMs incubated with IL 2 acquire strong cytotoxic activity against NK-resistant target cells. Although the mechanisms underlying these observations remain to be determined, the effector cells in these models have several similarities to those described by us in this report. For example, these effector cells can be generated by IL 2 in populations devoid of spontaneous NK activity and have neither the specificity nor the phenotypic markers of mature NK cells. The relationship of these effector cells with classic NK cells is unknown.

Several pathological conditions in addition to B-CLL have been found to have similar immunological abnormalities, including an inverted T4/T8 ratio, a poor response to T cell mitogen, and a loss of NK activity.[20-23] In the acquired immunodeficiency syndrome, Rook et al[23] have recently shown that the depressed NK activity present in PBMs of these patients cannot be restored by γ-IFN, but can be raised to normal levels by treatment with IL 2 sup. These results are identical to those obtained by us with B-CLL patients. Thus, it is possible that the defective NK activity present in B-CLL and other diseases could be overcome by in vitro treatment with IL 2.

Further studies are needed in order to understand (a) the relationship between the effector cells mediating NK activity and those generated in the presence of IL 2; (b) the significance of the T cell abnormalities in B-CLL; and (c) the potential immunotherapeutic use of lymphokines in this group of diseases.

ACKNOWLEDGMENT

We express our thanks to C. Lorences and G. Peraile for their excellent technical collaboration, to Dr Millan for the statistical analysis, and to Dr J.H. Kehrl for reviewing the manuscript. We also thank C. Aranda for technical assistance in the immunofluorescence analysis, Coulter Científica, S.A. (Madrid) for EPICS-C facilities, and Dr A. de la Hera for his advice.

Cytoskeleton Organization Is Aberrantly Rearranged in the Cells of B Chronic Lymphocytic Leukemia and Hairy Cell Leukemia

By Federico Caligaris-Cappio, Luciana Bergui, Luisa Tesio, Guelfa Corbascio, Franca Tousco, and Pier Carlo Marchisio

The organization of actin-containing microfilaments and vimentin-containing intermediate filaments has been investigated in B chronic lymphocytic leukemia (B-CLL), hairy cell leukemia (HCL), and normal B cells cultured in vitro under basal conditions and after induction with 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA). In uninduced B-CLL cells, F-actin was predominantly associated with dot-shaped structures scattered over the ventral membrane representing spotty close contact adhesion sites analogous to "podosomes" described in other cell types. On TPA induction, podosomes became clustered in sharply defined areas sitting in the cell center beneath the nucleus. In some cells, long actin-containing protrusions appeared. In HCL cells, F-actin was associated with thin microvilli responsible for the "hairy" appearance; occasional cells showed scattered podosomes. On TPA induction, HCL cells sprouted long dendritic processes rich in submembraneous F-actin, which made intertwined networks. Therefore, in both B-CLL and HCL cells, adhesion structures were present and the capacity for adhesion in vitro was marked, which might explain some peculiar clinical features of the diseases. Adhesion structures and adhesive properties never appeared in normal B cells. These data further support the notion that B-CLL and HCL, although clinically different, may share common biological features and suggest that in these disorders, cytoskeleton modifications may represent a hallmark of transformation.

A NUMBER OF MAJOR lymphocyte functions mediated by surface receptors are controlled by the cytoskeleton. These functions include blood-lymph recirculation, cell-cell interactions, and secretion of antibodies and lymphokines (for review, see refs 1 and 2).

The malignant cells of B chronic lymphocytic leukemia (B-CLL) and hairy cell leukemia (HCL) are characterized by abnormalities that suggest defects of cytoskeletal functions. B-CLL cells have low mobility,[3] show decreased capping by different ligands,[4-6] and are unusually susceptible to microtubule disrupting drugs.[7,8] HCL owes its name to the presence of many irregular projections protruding from the surface of cells, which are clearly visible in a phase contrast microscope and appear as irregular undulating ruffles or long villi when examined by the scanning electron microscope.[9] HCL cells are able to cap surface immunoglobulins (sIgs) and concanavalin A (ConA) receptors; the membrane redistribution of these structures is inhibited by cytochalasin B.[10,11]

The in vitro stimulation of B-CLL and HCL cells with the differentiation-promoting agent 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA) induces changes of morphology, cytoplasmic enzyme activity, and surface markers.[12-14] B-CLL cells acquire an irregular hairy cell-like appearance with ruffles and protrusions.[12,13] HCL cells become firmly attached to culture dish surfaces and exhibit fibroblast-like projections and stellate features.[12-14] Details of the action of TPA are not yet fully elucidated; recent evidence suggests that TPA permeates the plasma membrane and activates protein kinase C, mimicking the physiological activator diacylglycerol.[15,16] By such mechanism, some protein targets are phosphorylated and this leads to reorganization of the subsurface microfilamentous network.[17-21]

These observations provide the rationale for the present study, in which we have investigated the organization of the cytoskeleton of normal B, B-CLL, and HCL cells in the uninduced state and after TPA induction in vitro. The experimental approach was adopted to answer the following questions: (1) Can TPA induce a rearrangement of cytoskeletal structures in malignant B cells? (2) Are the peculiar morphological features of HCL, also reproduced by TPA treatment of B-CLL cells, dependent on cytoskeleton rearrangements? (3) Is the cytoskeleton of normal B cells behaving differently compared with its malignant counterparts under the same experimental conditions?

MATERIALS AND METHODS

Preparation of cells. Peripheral blood lymphocytes (PBLs) were obtained from 26 patients. Twenty-three patients (14 males, nine females; aged 49 to 70) had B-CLL: ten were in stage O-I, six in stage II, six in stage III, and one in stage IV, according to Rai.[22] In all cases, B lymphocytes expressed monoclonal Ig (k^+ or λ^+) with low intensity, formed rosettes with mouse red blood cells ($MRBC^+$), and were Tl antigen positive as detected by the monoclonal antibody RFTl.[23] None of the patients had received chemotherapy in the four months preceding the study. Three patients (all males aged 52 to 68) had HCL. The diagnosis was based on cell morphology, the presence of 50% to 75% tartrate-resistant acid phosphatase-positive ($TRAP^+$) cells in peripheral blood, and the bone marrow histology on trephine biopsies.

Mononuclear cells were separated from patients' peripheral blood samples on Ficoll-Hypaque (FH). Cells layered at the interphase were washed twice with phosphate-buffered saline (PBS) and resuspended in RPMI medium supplemented with 10% fetal calf serum (FCS). The percentage of monocytes was 1% to 4% in B-CLL samples and less than 1% in HCL samples.

Tonsils (three samples) were obtained from children undergoing tonsillectomy after antibiotic treatment and were teased with blunt forceps. Cell suspensions were washed with PBS and allowed to adhere to plastic for one hour. The nonadherent cells were rosetted with sheep red blood cells (SRBC) and spun onto FH for 30 minutes at room temperature. The cells at the interphase were collected and resuspended in RPMI containing 10% FCS and the percentage of

residual T cells was evaluated with Leu 4 (Becton Dickinson, Mountain View, Calif, cat. 7340). In one experiment, MRBC$^+$ cells were purified as previously detailed.[12,13] Briefly, 5×10^6/mL tonsil lymphocytes were incubated with 10^8/mL MRBCs as a pellet for five minutes at 37 °C and then for 30 minutes at 4 °C.[24] The cells, after gentle resuspension, were spun onto FH at 400 g for 25 minutes. The pelleted cells were treated with 0.1% Tris-NH_4Cl for 15 minutes at 20 °C to lyse RBCs and spun through FCS.

In vitro cultures. B-CLL, HCL, and normal B cells were resuspended in RPMI 1640 supplemented with 10% FCS at 1×10^6 cells per milliliter. Cells were cultured in vitro in 5-mL cultures and incubated for 72 hours on glass coverslips in 60-mm tissue culture dishes (Falcon, Oxnard, Calif) at 37 °C in a water-saturated atmosphere containing 5% CO_2. In each experiment, duplicate cultures were set up as controls and as TPA-stimulated samples. TPA was first dissolved in acetone (1.6 mmol/L) and then in absolute ethanol (0.016 mmol/L). The final TPA concentration in the cultures was 0.016 μmol/L, which previous experiments[12] had shown to be optimal for inducing phenotypic changes without major decrease in viability.

After 72 hours, the percentage of control uninduced B-CLL and HCL cells that showed spontaneous adherence to coverslips was 50% to 80%. The percentage of adherent TPA-induced B-CLL and HCL cells was more than 80%. Of the nonadherent cells, 10% to 20% were nonviable as assessed by trypan blue dye exclusion. On the contrary, almost all normal B cells were nonadherent, and the percentage of dead cells was 5% to 10%. The free-floating cells were harvested and glued onto poly-L-lysine–treated glass coverslips for 30 minutes. The slides were then washed briefly with PBS, allowed to dry, fixed and stained as described.

Fluorescence microscopy. Coverslip-attached cells were processed both for the expression of surface markers and for the analysis of cytoskeletal structures.

The expression of surface markers was investigated on air-dried, acetone-fixed cells stained in double fluorochrome immunofluorescence using mouse monoclonal antibodies (Mo Abs), followed by goat antimouse IgGs tagged with fluorescein isothiocyanate (FITC) and goat antihuman Ig isotypes tagged with tetraethylrhodamine isothiocyanate (TRITC). We used the B cell-specific Mo Abs B1 (Coulter cat. No. 6602140), B4 (Coulter, Hialeah, Fla, cat. NO. 6602683), RFB4[25] gift of Professor G. Janossy, London), the monocyte-reacting MO1 (Coulter, cat. No. 6602147), MO2 (Coulter cat. No. 6602141), UCHM1[26] (gift of Dr P. Beverley, London), and rabbit antisera to human Ig isotypes (μ, δ, γ, α, κ, λ) labeled with TRITC from Dakopatt (Glostrup, Denmark, cat No. R-152,R-148,R-151,R-153,R-154,R-155). MO1 and MO2 Abs are not monocyte-specific, since they react with granulocytes and bone marrow precursors.[27] Nevertheless, they are unreactive with normal and malignant B cells while detecting both normal and malignant monocytes.[28] Thus, MO1 and MO2 discriminate between B lymphocytes and cells of the monocyte-macrophage lineage.

The analysis of cytoskeletal structures was performed on coverslip-attached cells fixed in 3.7% formaldehyde (from paraformaldehyde) in PBS containing 2% sucrose for 5 minutes at room temperature. After rinsing in PBS, cells were permeabilized in PBS containing 0.5% Triton X-100 (BDH Chemicals, Ltd, Poole, England) for 5 minutes at room temperature and extensively rinsed.

F-actin–containing microfilamentous structures were stained for 30 minutes at 37 °C with rhodamine isothiocyanate-labeled phalloidin (R-PHD) dissolved in PBS containing 0.5% dimethyl sulphoxide. R-PHD, which has been shown to selectively bind to F-actin,[29] was a kind gift of Professor Th. Wieland, Heidelberg, FRG.

Vimentin-containing intermediate-type filaments were decorated by a mouse Mo Ab which has been shown to recognize vimentin of most animal species.[30] The vimentin antibody was used as hybridoma supernatant directly layered on detergent-permeabilized cells and incubated for 30 minutes at 37 °C. After rinsing with PBS, coverslips were incubated with either FITC- or TRITC-tagged rabbit antimouse IgGs (Dakopatt, cat. No. R-270) used at 0.1 mg/mL for 30 minutes at 37 °C. In some experiments, F-actin was simultaneously decorated by adding R-PHD (1 μg/mL) in the second antibody step.

Stained coverslips were mounted either in 50% glycerol in PBS or in Mowiol 4-80 (Hoechst, Frankfurt, FRG) and viewed with the appropriate filters in a Leitz Dialux epifluorescence microscope equipped with a Zeiss planapochromat 63×/1.4 oil immersion lens. For determining adhesion, PBS-glycerol–mounted coverslips were examined at 50× power in a Leitz Diavert microscope equipped for interference-reflection contrast.

Fluorescence photographs were recorded on Kodak Tri × films rated at 1250 ISO and developed in Gradual ST20 developer (Ornano, Milan). Interference reflection pictures were recorded on Agfa Ortho 25 films.

Finally, in each experiment, coverslip-attached cells were checked for the presence of nonspecific acid esterase with standard cytochemical methods.

RESULTS

Characterization of B cell populations. Normal tonsil B cells were strongly IgM$^+$ and did not form rosettes with MRBCs. The purified MRBC$^+$ cells were weakly IgM$^+$ and coexpressed the T1 antigen (RFT1$^+$). Both cell populations reacted with B1, B4, and RFB4 (95%) and did not stain with Mo1, Mo2, UCHM1 (1%). The phenotype was left essentially unchanged by TPA treatment.

B-CLL cells showed the typical features of weak surface Ig expression (80%) and MRBC positivity (60% ± 9%). In 21 of 23 cases, the monoclonal B cells were RFT1$^+$ (90%). All cases were also B1$^+$, B4$^+$, RFB4$^+$ (85%) and failed to react with Mo1, Mo2, UCHM1 (1%). After TPA, all cases lost sIg; B1, B4, and RFB4 reactivity became faint or was lost. As already shown in previous studies,[12,13] the T1 antigen expression was retained. Sixteen of 23 cases expressed cytoplasmic Ig of the same heavy and light chain expressed by fresh uninduced cells. In no instance was positivity with Mo1, Mo2, or UCHM1 recorded (less than 1%).

HCL cells were Ig$^+$, reacted with B1, B4, RFB4 (80%) but failed to stain with Mo1, Mo2, UCHM1 (5%). The phenotypic features were left essentially unchanged after TPA treatment. B-CLL and HCL cells, in both uninduced state and after TPA, never showed cytoplasmic nonspecific esterase enzyme activity.

Microfilaments in normal and TPA-induced human B lymphocytes. Substratum-attached human B lymphocytes appear as spherical cells provided with thin laminar slabs accounting for their attachment. The distribution of F-actin–containing microfilaments is difficult to document because of the rounded shape of cells, which is responsible for a uniform fluorescent signal associated with the plasma membrane (Fig 1A). After 72 hours' exposure to TPA, B cells tend to flatten on a poly-L-lysine substratum, giving rise to a polymorphic population in which F-actin is mostly associated to short peripheral protrusions. Such extensions are in the form of slender (Fig 1B) or thicker (Fig 1C) microvilli, flattened ruffles (Fig 1C and D), and thorns (Fig 1E). Occasionally, arrowhead-shaped protrusions containing

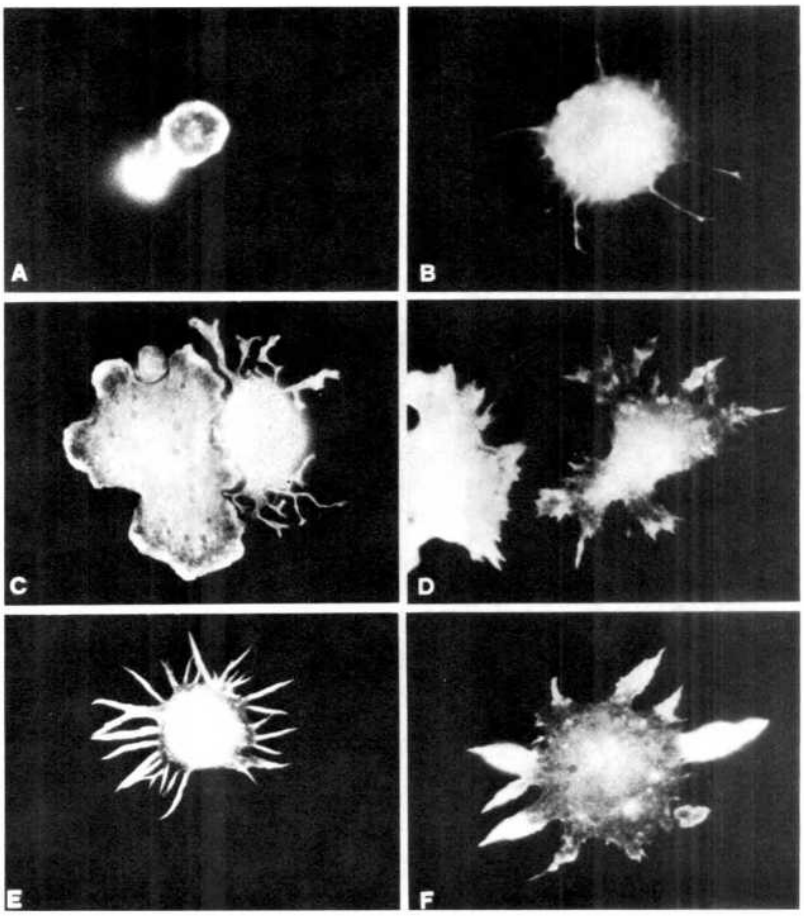

Fig 1. R-PHD fluorescence staining of F-actin in normal (A) and TPA-induced B cells (B through F). In normal B cells, F-actin is associated with the cytoplasmic face of the plasma membrane and gives rise to a thin line of peripheral fluorescence (A). After 72 hours' induction with TPA, B cells generally spread over the substratum and sprout multiple processes, showing different patterns of microfilamentous structures (original magnification ×3,500; current magnification ×2,275).

large amounts of F-actin sprout from the cell periphery (Fig 1F).

After TPA treatment, the general pattern of microfilaments suggests that B cells have arranged their actin-containing structures and have probably acquired motility properties that are not expressed before treatment. The marked polymorphism of TPA-treated B cells suggests analogy with the cytoskeletal pattern expressed by control HCL cells (see later).

Microfilaments in untreated B-CLL and HCL cells. In cultured B-CLL cells, three phenotypically variant forms can be identified. In each case examined, a small proportion (about 10%) of cells are rounded, and their appearance and staining pattern with R-PHD are barely distinguishable from control B lymphocytes (eg, Fig 1A). This cell population probably represents a variant that cannot achieve adhesion with the culture substratum. The size of this subpopulation may be underestimated because staining manipulations may have removed a considerable proportion of these cells.

The majority of cells (about 80%) shows a characteristic staining pattern with R-PHD. The main feature is the concentration of F-actin in multiple, rather regularly distributed dots that, by careful focusing, appear to be associated with the ventral membrane sitting in contact with the adhesion substratum (Fig 2A). When examined in the interference reflection microscope, which measures the distance between cells and the adhesion substratum,[31,32] these dots appear to correspond to close contact areas (Fig 2B). In these cells, the nucleus is mostly centrally located (Fig 2C). Further evidence that actin-containing dots are associated with punctate adhesion sites can be inferred from the fact that, when cells are gently streamed with a jet of buffer before fixation, dots remain attached to the substratum and leave a footprint of the cell ventral membrane.[33]

In a third subpopulation, representing a minority of attached cells (about 10%), the dots are absent, but the general shape is more irregular because polymorphic protrusions sprout from the cell surface. Such pattern is similar to that exhibited by TPA-induced normal B lymphocytes (see Fig 1B through F) and represents the main phenotype of in vitro HCL cells (see later). B-CLL cells showing mixed features, ie, both dots and processes, are observed with low frequency (less than 5%).

As a rule, the majority of control HCL cells show a wealth of protrusions in the form of filopodia and ruffles, which are located both at the peripheral rim and over the dorsal surface (Fig 3A). Such protrusions are clearly visible on fluorescent PHD-stained cells on the basis of their rich F-actin content. A minor fraction of HCL cells (around 20%; Fig 3B) show dot-like accumulations of F-actin at the ventral membrane similar to those shown by the majority of B-CLL cells and some thin microfilament bundles (Fig 3B). Cells showing both dots and membrane protrusions (eg, Fig 3C) are infrequently observed (about 5%).

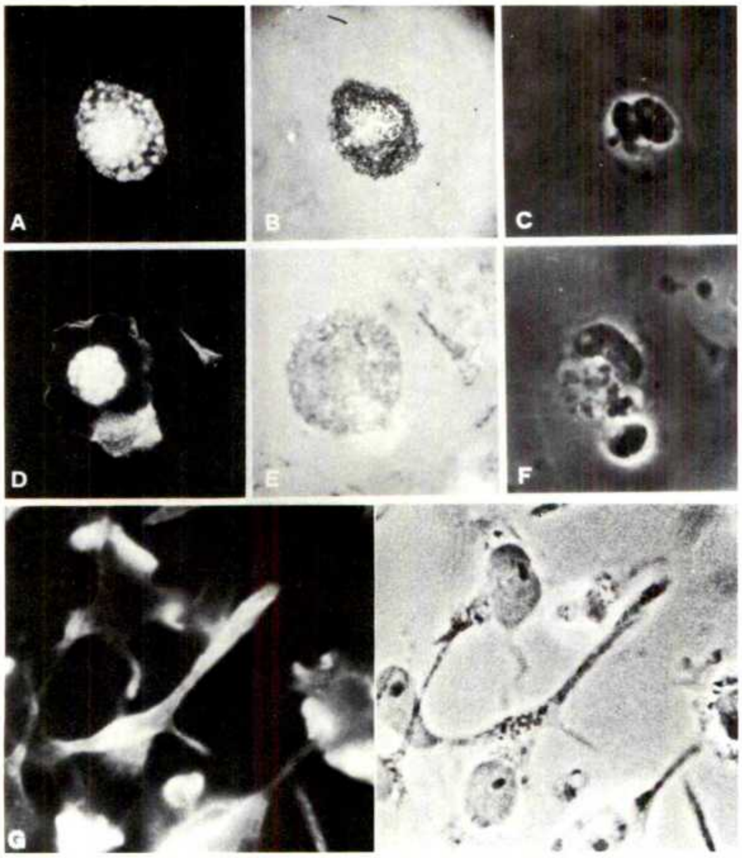

Fig 2. R-PHD fluorescence staining of F-actin in uninduced (A) and TPA-induced B-CLL cells (D, G). Interference reflection and phase contrast pictures of the same cells are shown, respectively, in (B) and (E) and in (C), (F), and (H). In uninduced B-CLL cells (A), actin-containing podosomes are scattered all over the ventral membrane and give rise to a grayish pattern of close contact in the interference reflection microscope (B). The nucleus is apparently located in the cell center (C). After TPA induction, podosomes cluster in a sharply defined area (D) that corresponds to spotty close contacts (E). The nucleus is generally displaced outward by the cluster of podosomes, suggesting that these structures extend deeper in the cytoplasm of these cells (F). A nonadherent cell overlying the flattened one is out of focus and barely visible (lower right) in (D), (E), and (F). In some induced B-CLL cells, sprouting of long dendritic processes takes place (G and H). Such a pattern is identical to that induced by TPA in HCL cells (see Fig 3). (Original magnification ×3,500; current magnification ×2,275)

Changes of microfilament pattern induced by TPA treatment in B-CLL and HCL cells. TPA treatment induces marked changes in the microfilament distribution of B-CLL and HCL cells. The most remarkable effect in B-CLL cells is the constant clustering of the dot-like accumulations of F-actin observed in untreated cells, which comes along with considerable flattening and improvement of adhesion (Fig 2D). Clusters of dots are usually positioned in the area below the nucleus but may be eccentric or clearly displace the nucleus, which sometimes acquires a bean-like shape (Fig 2F). In the interference reflection microscope, a broad close contact area appears to be coincident with the cluster of dots (Fig 2E) and often extends beyond it. The clustering of dots is a regular event on TPA treatment and can be observed in most cells in the vast majority of cases.

In a number of B-CLL samples (about 30%), TPA treat-

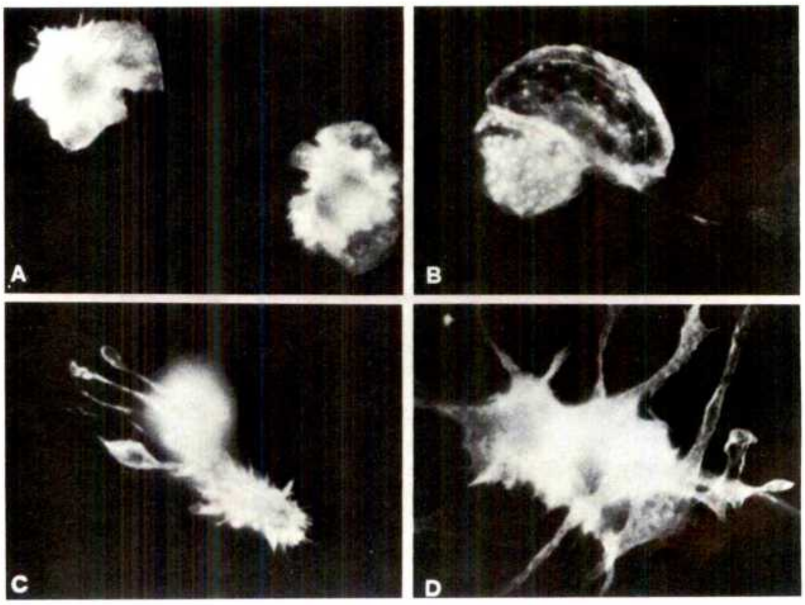

Fig 3. R-PHD fluorescence staining of uninduced (A through C) and TPA-induced (D) HCL cells. Uninduced HCL cells show a polymorphous pattern of ruffles and peripheral protrusions, justifying the "hairy" appearance. Some cells show obvious podosomes (B, lower left) and, occasionally, thin microfilament bundles (B, upper right). On TPA induction, HCL cells sprout long processes that make intertwined networks reminiscent of some tissue cultures of nerve cells (D). (Original magnification ×3,500; current magnification ×2,275)

ment induces also the appearance of polymorphic stellate cells whose long processes form a complex intertwined network (Fig 2G and H). Within such network, scattered cells with clustered dots are sometimes found together with intermediate forms, thus suggesting that cells showing either stellate appearance or clustered dots may represent a continuum of interchangeable forms (not shown).

In all three cases of HCL examined, TPA treatment induces the appearance of stellate cells forming an intricate dendritic network (Fig 3D). Microfilaments are associated with the membrane in polymorphic protrusions. The presence of clustered F-actin dots is never observed in TPA-treated HCL cells.

Distribution of vimentin-type intermediate filaments in normal B, B-CLL, and HCL cells. Substratum-attached normal B lymphocytes have intermediate filaments of the vimentin type located in the thin perinuclear cytoplasmic area (Fig 4A). After TPA treatment, along with cell flattening, intermediate filaments tend to form curly bundles extending within the cytoplasmic lamina but never reach the edge of the cell (Fig 4B). Those cells that just extend thin filopodia never show vimentin within such extensions.

In double-labeled B-CLL cells, complete independence exists between the network of vimentin filaments and the distribution of F-actin dots. Accurate focusing suggests that intermediate filaments lay in an upper layer within the cell.

Vimentin filaments form intricate networks in flattened B-CLL or HCL cells (Fig 4C) and do extend into elongated cellular processes of these cells after TPA induction (Fig 4D).

DISCUSSION

The close association between lymphocyte receptor function and the cellular contractile system has focused attention on lymphocyte cytoskeleton (for review, see refs 1 and 2). Both normal and malignant lymphoid cells have been analyzed, and several reports have detailed the biochemistry and function of cytoskeletal proteins in B-CLL and HCL.[34-38] The present study was undertaken to evaluate the organization of some cytoskeletal structures in HCL and B-CLL cells, as well as in normal B cells, and the rearrangements that might occur on activation in vitro. Our approach has been to study cultured adherent cells at rest or after activation with TPA. The rationale of this approach is threefold. First, adherent cells allow a detailed analysis of intracellular filamentous networks. Second, TPA has been shown to influence both shape and motility of different cell systems.[39] Finally, a close lineage relationship has recently been established between B-CLL and HCL by culturing the malignant cells in vitro in the presence of nanogram TPA concentrations and demonstrating that TPA-induced B-CLL cells acquire the typical morphology, enzyme activity, and surface markers of HCL cells.[12,13]

Our first observation is that circulating uninduced HCL cells already have an altered organization of the microfilament pattern, since they show a wealth of peripheral microvilli, which account for their "hairy" appearance. These are absent in both normal and other neoplastic B cells. TPA stimulation emphasizes such pattern by producing long dendritic processes in which intermediate filaments also grow.

The peculiar organization of the cytoskeleton in HCL may explain the tendency of these cells to adhere spontaneously in vitro without any artificial "coating" of the substratum. The in vitro adhesive properties of HCL cells may provide an explanation for the peculiar clinical behavior of the disease, which, in its typical form, presents very low numbers of circulating malignant cells but a marked infiltration of both bone marrow (BM) and peripheral lymphoid organs, notably the spleen.[40,41] B-CLL cells relentlessly accumulate in the BM and lymphoid organs and fail in large part to recirculate.[42] These cells, when cultured in vitro, adhere spontaneously to glass coverslips and do show adhesion structures. Our in vitro data may represent the experimental counterpart of the B-CLL sluggish recirculation in vivo.

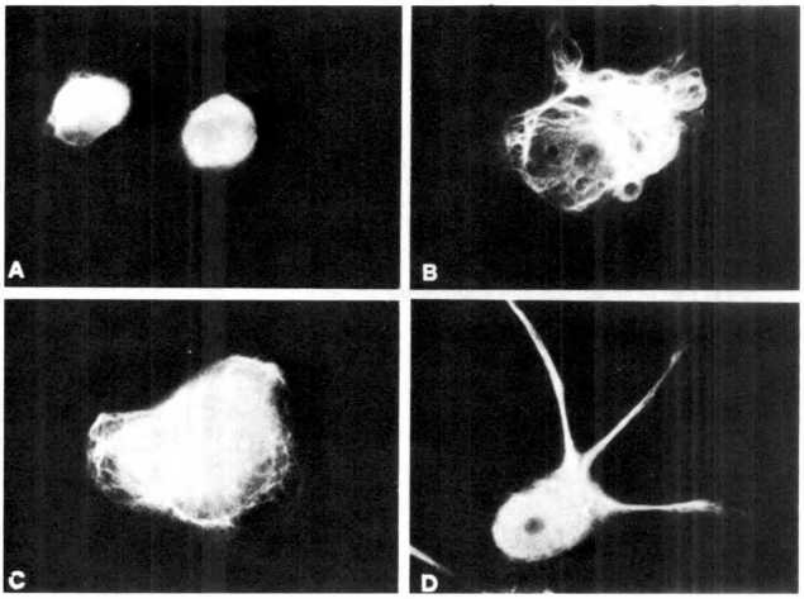

Fig 4. Immunofluorescence localization of vimentin in uninduced (A) and TPA-induced B cells (B), B-CLL (C), and HCL cells (D). Individual vimentin filaments cannot be resolved in normal B cells (A), while they can be observed after induction (B) also in B-CLL cells (C). Vimentin filaments do not extend into thin cellular processes but do so in the long dendritic extensions of TPA-induced HCL cells (D). (Original magnification ×3,500; current magnification ×2,275)

The second observation is that the substratum adhesion of B-CLL cells is not mediated by the conventional focal contacts (also called "adhesion plaques") described in other cell types, eg, in fibroblasts.[43] Rather, adhesion is mediated by dot-shaped close contacts that have been earlier described in a variety of transformed cells[44-46] and recently characterized and called podosomes.[33] Podosomes concentrate the bulk of cellular actin and other cytoskeletal proteins in short protrusions of the ventral membrane identified by electron microscopy.[33] In B-CLL cells, the major portion of cellular F-actin is localized in podosomes, but some is found also submembraneously in peripheral and dorsal ruffles. There is a substantial lack of bundled microfilaments, and therefore, stress fibers are not observed.

The expression of podosomes and the distribution of cytoskeletal proteins appear as a continuum in uninduced B-CLL, TPA-induced B-CLL, and HCL cells. This finding further supports the existence of a close link between B-CLL and HCL. However, some points still have to be clarified. In uninduced B-CLL cells, podosomes are scattered, but after induction, they consistently cluster in a sharply defined area of the ventral membrane sitting beneath the nucleus and sometimes displacing it. The mechanism(s) that governs this event is unknown. Unknown as well is the reason why some cases of TPA-induced B-CLL cells sprout long dendritic processes identical to those shown by HCL cells after TPA. Also, the relationship between podosomes and dendritic processes bringing about a full redistribution of intracellular actin is not yet understood. The mechanics of these events should be looked for in the pleiotropic actions of TPA (for review, see refs 21 and 39) and in the largely unknown cascade of events following the activation of protein kinase C.[15,16]

The third observation is that bona fide podosomes are not observed in normal lymphocytes at rest or after TPA induction. So far, the only nontransformed cells that have been shown to adhere by means of podosomes are osteoclasts[47] and some monocyte-derived cells, including macrophages (ref 48 and P.C. Marchisio, F.G. Giancotti, A. Tefi, A. Zambonin-Zallone, and G. Tarone, manuscript in preparation). However, the number of monocytes in our samples was almost negligible compared with the number of adherent cells. Also, monocytic markers could not be detected in B-CLL cells both uninduced or after TPA treatment. B-CLL cells express monoclonal Igs on their surface or within the cytoplasm and stain with the B cell-specific Mo Abs B1, B4, and RFB4. They fail to react with the monocyte-specific Mo Abs Mo1, Mo2, and UCHM1 and do not exhibit cytoplasmic nonspecific esterase activity. HCL cells have been shown by gene rearrangement studies to belong to the B cell lineage,[49,50] although with some unusual features, such as a strong adhesive tendency (but see earlier) and the ability to phagocyte latex particles.[51] They are also nonspecific esterase negative.

In conclusion, podosomes are adhesion structures that appear associated with B-CLL and (partially with) HCL malignant B lymphoid cells but are absent in their normal counterparts. It is, therefore, important to point out that podosomes have been found also in mammalian and avian cells transformed by Rous sarcoma virus.[33,44-46] In transformed cells, podosomes are peculiar adhesive structures that concentrate tyrosine-phosphorylated proteins,[4] including the specific tyrosine kinase pp60v-src.[45] Thus, it is tempting to suggest that these cytoskeletal structures may represent one hallmark of transformation also in B-CLL cells. The transformation of a normal B lymphocyte into a neoplastic B-CLL cell might be marked by a rearrangement of its membrane-microfilament interactions, leading to the appearance of novel adhesion properties. Whether the expression of cellular oncogenes is responsible for the whole pattern of cytoskeletal changes in these cells is a promising avenue for future investigations.

Platelet Modulation of Polymorphonuclear Leukocyte Shear Induced Aggregation

By Byung-geon Rhee, Elizabeth R. Hall, and Larry V. McIntire

A cone and plate viscometer and Coulter Counter were used to study platelet modulation of polymorphonuclear leukocyte (PMNL) aggregation caused by controlled shear stress. As an index of aggregation, the large-particle percentage (LPP) was calculated. This represents the ratio of aggregated cell count to total cell count. PMNL suspensions in buffer (1.0×10^7 cells per milliliter, final concentration) did not show any aggregate formation at shear stresses below 150 dynes/cm^2 for one minute exposure time (LPP $<$ 3%). However, there was PMNL aggregation in mixed PMNL and platelet-rich plasma suspensions in this shear stress range. Supernatant plasma from sheared platelets initiated PMNL aggregation at moderate shear stress (150 dynes/cm^2 for one minute; LPP, 20.3% ± 2.5%). In contrast, platelet release factors, such as adenosine diphosphate (2 μmol/L) and serotonin (2 μmol/L) did not cause PMNL aggregation (LPP, 2.9% ± 1.2% and 3.3% ± 0.8%, respectively). The use of a cyclo-oxygenase inhibitor (acetylsalicylic acid, 50 μmol/L) did not suppress the aggregation of PMNLs after shear (LPP, 20.1% ± 2.4%). However, preincubation with nordihydroguaiaretic acid (10 μmol/L), an inhibitor of C-5 and C-12 lipoxygenase, and 6,9-deepoxy-6,9-(phenylimino)-6,8-prostaglandin I_1 (U-60257, 10 μmol/L), an inhibitor of C-5 lipoxygenase in human leukocytes, suppressed this aggregation (LPP, 9.1% ± 2.5% and 10.4% ± 3.2%, respectively). Also, the formation of lipoxygenase products (5-HETE, 12-HETE, 15-HETE, and LTB_4) activated by shear stress was documented by reversed phase-high-performance liquid chromatography (RP-HPLC). These data support the possibility of a cooperation between platelets and leukocytes in shear-induced PMNL aggregation that is dependent on C-12 or C-5 lipoxygenase activity, or both.

POLYMORPHONUCLEAR leukocytes (PMNLs) are a central component of cellular response in inflammatory reactions and of paramount importance to the immune surveillance system. These phagocytic cells contain diverse tissue-destroying and microbicidal enzymes and proteins. Chemotactic factors appear pivotal in this migratory process. Many chemotactic factors have been described, but those derived from the fifth component of complement (eg, C5a and des-Arg-C5a) and synthetic analogues of the putative bacterial chemotactic factor (eg, *N*-formyl peptides) have been most thoroughly characterized.[1-6] These agents, in the nanomolar concentration range, bind and activate the PMNLs by interacting with distinct receptor sites to induce directional migration of the PMNLs. They also stimulate other cellular functions, such as aggregation, adherence, enzyme release, and the production of toxic oxygen metabolites. Thus, in addition to attracting PMNLs, chemotactic factors appear capable of modulating a number of other aspects of the inflammatory reaction. Several chemotactic factor-induced PMNL aggregation studies have been performed, initially stimulated by the observation of neutropenia in extracorporeal hemodialysis and endotoxemia. Neutropenia, pulmonary sequestration, and arterial hypoxemia are all transient phenomena exhibiting a time course that appears to parallel that of PMNL aggregation in vitro.[1-3]

Fluid shearing is known to produce cell interactions and, in whole blood, can lead to platelet–leukocyte aggregation.[7,8] However, no studies have been reported of shear-induced PMNL aggregation under controlled fluid mechanical conditions. Improved designs for artificial organs and prostheses require more detailed knowledge of thromboembolic phenomena produced by mechanical trauma and biomaterial surface exposure. Shear stresses of greater than 150 dynes/cm^2 can be generated during blood flow through hemodialysis devices, artificial heart valves, and blood oxygenators. Unfortunately, the complex and variable shear stress histories that cells experience in cardiopulmonary bypass and other circulatory support systems are hard to quantitate. Therefore, to generate an understanding of the role of leukocytes in embolic phenomena initially requires performing experiments in which the fluid forces are well known. In vitro studies of shear stress and surface interaction effects have normally used simpler flows, including stagnation point flow, flow through tubes, and flow in rotational viscometers. In this study, a rotational cone and plate viscometer was used for the purpose of applying a known uniform shear stress to the entire sample volume.

PMNLs may participate along with platelets in hemostasis and thrombosis.[7,9] In platelets, the cyclo-oxygenase pathway of arachidonic acid metabolism has been implicated in these processes. Platelets also have a pathway involving lipoxygenase action on arachidonic acid, which forms (12S)-12-hydroperoxy-5,8,10,14-eicosatetraenoic acid (12-HPETE) and, subsequently, the corresponding (12S)-12-hydroxy acid (12-HETE).[10-12] The main pathway of arachidonic acid metabolism in neutrophils involves 5-lipoxygenation, leading to the formation of eicosanoids such as leukotrienes (LTs) and other hydroxy acids.[13-16] The discovery of LTs, a new family of bioactive metabolites formed in a lipoxygenase—type reaction (involving the C-5 of arachidonic acid), and the detection of a C-15 lipoxygenase in leukocytes have indicated the existence of several lipoxygenase enzymes in blood cells. Arachidonic acid does not normally exist in free form but is usually esterified in

triglycerides and phospholipids. Stimulated phospholipases can release arachidonic acid, which is then enzymatically metabolized by the 5-lipoxygenase pathway to form LTs as well as a host of other bioactive metabolites.[16–18] In addition to differences in positional specificities, the heterogeneity of these enzymes is further emphasized by different reactivities. For instance, it has been shown that, in contrast to platelet suspensions, which can efficiently transform exogenous arachidonic acid into 12-HETE and cyclo-oxygenase products, the addition of the fatty acid to preparations of human PMNLs was followed by only minor transformation of the substrate.[4,13] However, the metabolism of arachidonic acid was strongly enhanced when leukocytes were incubated in the presence of arachidonic acid and divalent cation ionophore A23187, indicating clearly that the human PMNL C-5 lipoxygenase required activation for 5-HETE and LT synthesis. Maclouf et al[10] have shown that platelet-derived 12-HPETE can stimulate this C-5 lipoxygenase. Recent studies suggest the involvement of LTs in hypersensitivity reactions and inflammation and point out the importance of a better understanding of the biochemical process involved in the control of the biosynthesis of these bioactive substances.[13,19–23]

To begin to understand the biochemical control mechanisms of shear-induced PMNL aggregation, we have used inhibitors of cyclo-oxygenase or lipoxygenase (acetylsalicylic acid [ASA], nordihydroguaiaretic acid [NDGA], U-60257), synthetic chemotactic tripeptide formyl-methionyl-leucyl-phenylalanine (FMLP), and calcium ionophore A23187. The effect of these factors in PMNL aggregation in the presence or absence of platelets and shear-activated platelet-released products suggests the occurrence of significant biochemical interactions between platelets and leukocytes in mechanically induced activation processes.

MATERIALS AND METHODS

Preparation of human PMNLs. Venous blood from normal healthy donors was drawn by venipuncture into heparin (10 U/mL, final concentration) in conical plastic tubes. PMNLs were purified using standard techniques of dextran sedimentation, centrifugation on Ficoll-Hypaque, and hypotonic lysis of erythrocytes. Final cell suspensions contained a minimum of 95% PMNLs. Viability of the PMNLs was always greater than 95% as determined by trypan blue exclusion. PMNLs were labeled with 5.5 µmol/L of 1-^{14}C arachidonate added during the first wash.

Preparation of platelet-rich plasma (PRP). Blood was obtained by venipuncture of healthy volunteers. Ten milliliters of blood was quickly and gently mixed with 1.1 mL of heparin (100 U/mL) in siliconized glass tubes. The heparinized blood was centrifuged for ten minutes at 150 g. The supernatant PRP was drawn off with a Pasteur pipette and transferred to a clean siliconized glass or plastic test tube. The remaining fractions were centrifuged for five minutes at 150 g to retrieve more PRP. Finally, the red blood cell fraction was centrifuged for ten minutes at 1,000 g. The resultant supernatant was platelet-poor plasma (PPP) and was transferred to a separate test tube. Platelet counts in all PRP samples were adjusted to 3×10^8/mL, final concentration, by dilution with PPP.

Reagents and buffers. 1-^{14}C Arachidonate (52.0 mCi/mmol, specific activity), ^{3}H 6-keto PGF$_{1\alpha}$, ^{3}H thromboxane B$_2$, ^{3}H PGF$_{2\alpha}$, ^{3}H PGE$_1$, ^{3}H PGE$_2$, and ^{3}H PGD$_2$ were all purchased from New England Nuclear (Boston). 5-HETE radioimmunoassay kit was purchased from Seragen (Boston). A23187, adenosine diphosphate (ADP), ASA, NDGA, FMLP, cytochalasin B, and colchicine were purchased from Sigma Chemical Co (St Louis). A23187, NDGA, FMLP, and colchicine were dissolved in dimethylsulfoxide (DMSO). Cytochalasin B and ASA were prepared in ethanol. The 6,9-deepoxy-6,9-phenylimino-6,8-prostaglandin I$_1$ (U-60257) was kindly provided by Dr M.K. Bach of the Upjohn Company and prepared in tris(hydroxymethyl)aminomethane (THAM). The small amount of ethanol and DMSO (final concentration of 0.1%) used as vehicles did not alter cell viability. The buffer was Dulbecco's phosphate-buffered saline (PBS) containing (mmol/L): NaCl (137), KCl (2.7), $Na_2HPO_4 \cdot 7H_2O$ (8.1), KH_2PO_4 (1.9), $CaCl_2$ (0.9), and $MgCl_2 \cdot 6H_2O$ (0.5).

Aggregation assay. The isolated PMNLs were suspended (1×10^7 cells per milliliter) in PBS and incubated according to the various procedures described under Results. After one minute of shearing at 150 dynes/cm^2, 20-µL samples were taken from the suspensions. The samples were immediately diluted in 10 mL of Isoton solution (Coulter Electronics, Hialeah, Fla) and analyzed in the Coulter Counter system. The Coulter Counter was a Model ZBI and was connected to Coulter Channelyzer and microcomputer. For each sample, the particle concentration was enumerated with a lower channel of 150 µm^3 (called the total or "T" particle concentration) and with a lower channel of 540 µm^3 (called the aggregated or large "A" particle concentration).[1,2] These names are given because with the lower channel of 150 µm^3, all PMNLs in a sample were counted, whereas with a lower channel of 540 µm^3, only particles larger than 1.8 times the size of an average unaggregated PMNL were enumerated. Results for a given sample of the PMNL suspension were reported as the large-particle percentage ($LPP = A/T \times 100$) or the maximum large-particle percentage. Sheared samples (and others incubated with various chemicals) were analyzed at ten-minute intervals to follow the aggregation process. The maximum large-particle percentage was the peak value of LPP obtained over the 60-minute aggregation interval.

Shear stress application. Leukocyte suspensions and PRP were subjected to shear stress in a specially modified Ferranti-Shirley Viscometer.[8] The platens used gave a cone and plate geometry. Thus the entire sample experienced the same constant shear stress. After shearing PRP for one minute at 150 dynes/cm^2, the sample was removed and rapidly centrifuged to produce a platelet-free supernatant. This supernatant plasma was added to PMNL suspensions within 30 seconds.

High-performance liquid chromatography (HPLC) analysis of icosanoids. In preparation for reversed phase-HPLC (RP-HPLC), cell suspensions were extracted by using Sep-PAK C18 cartridges

Table 1. The Mixing Ratio and Flow Rate Changes in the HPLC

and 90% methanol eluates were evaporated under nitrogen. Residues were dissolved in 100 μL of methanol, and 10 μL was injected onto the HPLC column. RP-HPLC was carried out on a 4-mm ID μ-PAK C18 (5 μm) column (Varian Assoc Instrument, Palo Alto, Calif) with water–methanol–acetronitrile as the eluting solvent. Table 1 gives the mixing ratio and flow rate changes as functions of elution time. Fractions were collected, and the radiolabel content of each was determined in Hydrofluor by liquid scintillation counting. Identification of the peaks was done by comparison with standards. Under these conditions, stable cyclo-oxygenase products 6-keto prostaglandin $F_{1\alpha}$ (6-keto $PGF_{1\alpha}$), thromboxane B_2 (TXB_2), $PGF_{2\alpha}$, PGE_1, PGE_2, and PGD_2 were eluted at four to ten minutes; LTB_4 at 20 to 22 minutes; mono-HETEs at 40 to 52 minutes, and unreacted arachidonate at 55 to 60 minutes.

RESULTS

Chemotactic factor and ionophore-induced PMNL aggregation. FMLP, as previously described by others,[1,2] aggregated human PMNLs. This effect was reflected in an increase in the percentage of large particles formed after adding 1 μmol/L FMLP to the suspension of PMNLs (Fig 1). Cytochalasin B, by itself, did not aggregate the cells but did significantly enhance FMLP-induced aggregation (Fig 1). The calcium ionophore A23187 (10 μmol/L) aggregated PMNLs (Fig 1), and the time course of aggregation was similar to that of shear-induced PMNL aggregation in the presence of supernatant from sheared PRP (see below). The kinetics of FMLP-induced aggregation reached nearly a maximum LPP within two to three minutes. However, the time course of ionophore A23187- and shear-induced aggregation was much slower, and a maximum value was not attained for over 30 minutes.

Shear-induced PMNL aggregation. PMNL suspensions in PBS (1×10^7 cells per milliliter, final concentration) did not show any aggregate formation at shear stresses below 150 dynes/cm^2 for one minute (Figs 2 and 3). However, when PMNLs were incubated in the presence of PRP, a strong stimulation of PMNL aggregation occurred in this shear stress range. PMNLs incubated with supernatant plasma from sheared platelets (1:1 by volume) would initiate PMNL aggregation after exposure to moderate shear stress (150 dynes/cm^2 for one minute, Figs 2 and 3). The effect of plasma protein on the shear-induced PMNL aggregation was examined by using the PMNL suspensions mixed with platelet-free plasma (PFP) (1:1 by volume, Figs 2 and 3). Platelet release factors, 2 μmol/L ADP or 2 μmol/L serotonin, did not induce PMNL aggregation at this shear stress (Fig 3).

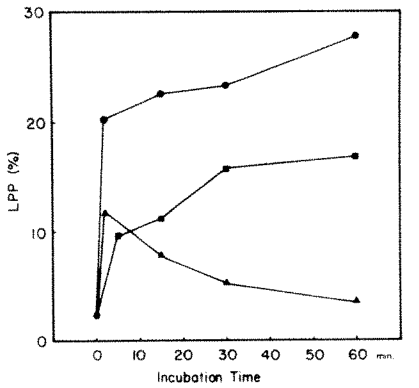

Fig 1. The kinetics of the chemotactic factor and ionophore-induced PMNL aggregation. PMNLs (1×10^7 cells per milliliter) were incubated with 1 μmol/L FMLP (▲) and 10 μmol/L A23187 (■) for the specific time periods. PMNLs were preincubated with cytochalasin B (5 μg/mL) for five minutes and then incubated with 1 μmol/L FMLP (●).

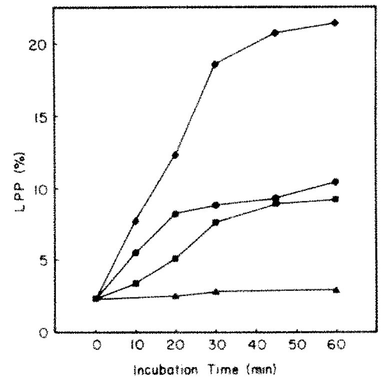

Fig 2. The kinetics of the shear-induced PMNL aggregation. PMNLs (▲), PMNLs mixed with platelet-free plasma (PFP) (●), PMNLs mixed with supernatant plasma of sheared platelets (2.5 to 4.0×10^8 cells per milliliter) (♦), and the last sample preincubated with 10 μmol/L NDGA (■) were sheared at 150 dynes/cm^2 for one minute. After shearing, samples were analyzed at ten-minute intervals for one hour to follow the aggregation process.

To define the nature of the factor(s) responsible for the effect of sheared platelet supernatants on leukocyte aggregation activity, experiments with inhibitors were performed. The inhibition of the cyclo-oxygenase pathway by 50 μmol/L ASA did not suppress the aggregation of PMNLs after shear (Fig 4). However, preincubation with NDGA (10 μmol/L), an inhibitor of C-5 and C-12 lipoxygenase, and U-60257 (10 μmol/L), an inhibitor of C-5 lipoxygenase in human leukocyte,[24,25] suppressed the aggregation of PMNLs (Figs 2 and

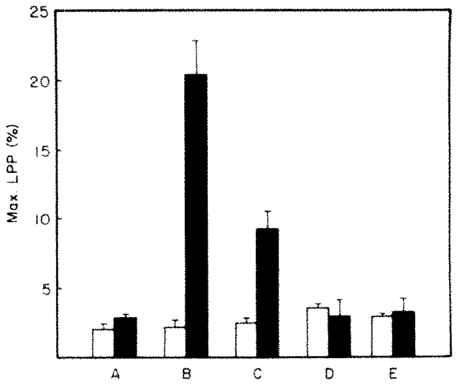

Fig 3. Effect of platelet release products on shear-induced PMNL aggregation. (A) PMNLs in buffer alone, (B) PMNLs mixed with supernatant plasma of sheared platelets, (C) PMNLs mixed with PFP, (D) PMNLs incubated with 2 μmol/L ADP, and (E) PMNLs incubated with 2 μmol/L serotonin. Sheared samples (150 dynes/cm^2 for one minute, closed bar) were compared with control samples (unsheared, open bar). Data represent the mean ± SEM for three to nine separate experiments and are the maximum LPP over a one-hour interval after shear exposure.

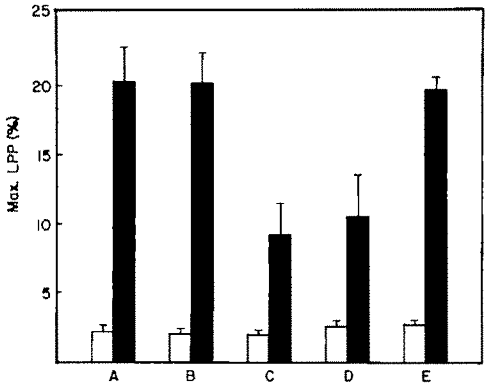

Fig 4. Effect of cyclo-oxygenase and lipoxygenase-inhibitors on PMNL shear-induced aggregation. PMNLs were mixed with supernatant plasma of sheared platelets and incubated with no inhibitors (A), ASA (50 μmol/L) (B), NDGA (10 μmol/L) (C), U-60257 (10 μmol/L) (D). In (E), PRP was incubated with imipramine (1 μmol/L) and sheared, and subsequently, the PMNLs were mixed with this supernatant. Sheared samples (150 dynes/cm² for one minute, closed bar) were compared with control samples (open bar). Data represent the mean ± SEM for three to nine separate experiments.

4). Supernatant of sheared PRP, which had been preincubated with NDGA (10 μmol/L), also suppressed subsequent shear-induced PMNL aggregation (data not shown).

PRP incubated with imipramine (1 μmol/L), an inhibitor of serotonin uptake, for 15 minutes was sheared and centrifuged. In this case, serotonin that was released from sheared PRP was in the supernatant. PMNLs incubated with this supernatant did not show any change in the shear-induced PMNL aggregation (Fig 4). These data all suggested that serotonin had no effect in the shear-induced PMNL aggregation. In addition, incubation of PMNL with ADP (2 μmol/L) did not induce aggregation, with or without shear stress. Fig 5 shows the effect of shear stress magnitude on PMNL aggregation for three different samples.

Effect of platelet-PMNL ratios. When PMNL and PRP (1:1 by volume) samples were sheared at 150 dynes/cm² for one minute, there were differences in the aggregation profiles dependent on the ratio of platelets to PMNLs (Fig 6). When the ratio was approximately 30, the aggregation response of PMNL was maximum. At this ratio, the total volume of platelets was nearly equivalent to that of PMNLs. Also, this ratio is nearly the same as that found physiologically.

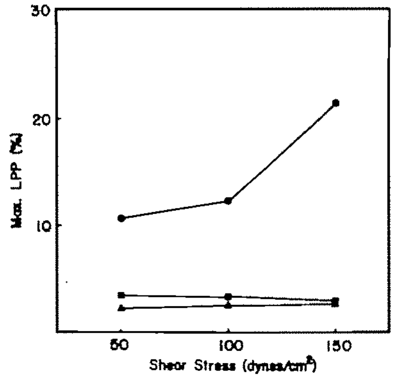

Fig 5. Effect of shear stress magnitude on the maximum LPP. Three shear stresses (50, 100, and 150 dynes/cm²) were used to shear PMNLs in buffer (▲), PMNLs incubated with 2 μmol/L ADP (■), and PMNLs mixed with supernatant plasma of sheared platelets (●).

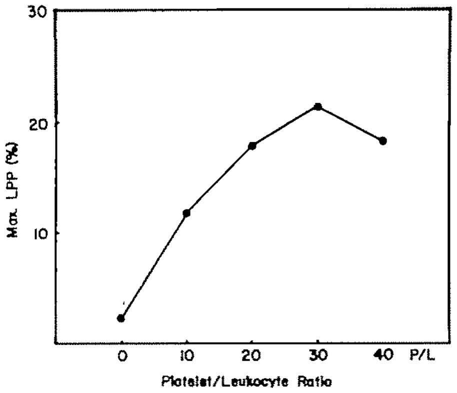

Fig 6. Effect of platelet concentration on shear-induced PMNL aggregation. Different platelet concentrations in PRP were sheared and centrifuged. This supernatant plasma was added to PMNL suspensions (1 × 10⁷ cells per milliliter) and, subsequently, sheared at 150 dynes/cm² for one minute.

HPLC experiments. Studies of platelet or PMNL arachidonate metabolites, identified by HPLC, were used to examine the details of arachidonic acid metabolism under shear stress. Results of a group of experiments analyzed by RP-HPLC are shown in Figs 7 through 10.

PMNL suspensions mixed with 5.5 μmol/L 1-^{14}C arachidonic acid and supernatant of sheared PRP generated a significantly increased quantity of LTB$_4$ after shearing, which appeared as a distinct peak (retention time, 21 minutes), as shown in Fig 7. When PMNL suspensions were preincubated with 10 μmol/L NDGA, there was no significant increase of LTB$_4$ formation after shearing (Fig 8). Only 12-HETE formation was increased when PRP and 5.5

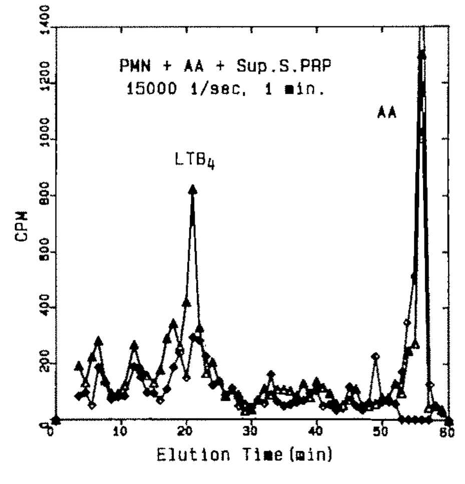

Fig 7. RP-HPLC chromatogram of the metabolites of arachidonic acid formed in human PMNLs incubated with 5.5 μmol/L 1-^{14}C arachidonic acid in the presence of supernatant of sheared PRP. Control (◇) and after shearing at 150 dynes/cm² for one minute (△).

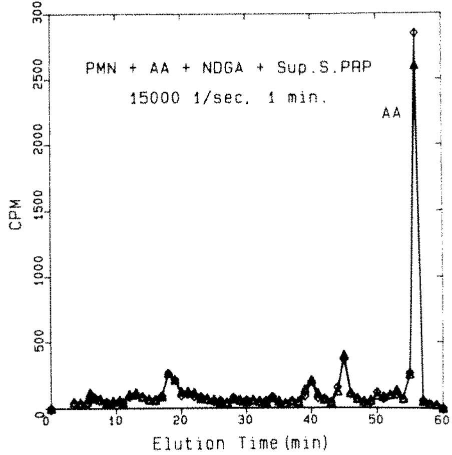

Fig 8. RP-HPLC chromatogram of the metabolites of arachidonic acid formed in human PMNLs preincubated with 10 μmol/L NDGA and with 5.5 μmol/L 1-^{14}C arachidonic acid in the presence of supernatant of sheared PRP. Control (◇) and after shearing at 150 dynes/cm^2 for one minute (△).

μmol/L 1-^{14}C arachidonic acid were exposed to shear stress (Fig 9). That this metabolite was 12-HETE, not 5-HETE, was confirmed by using thin-layer chromatography (data not shown). Little cyclo-oxygenase products were detected after shear stress stimulation of platelets. The amount of TXB_2 formation after shear stress stimulation of platelets measured by radioimmunoassay was ≤10 ng/10^8 platelets. The counts per minute (cpm) range corresponding to this concentration was nearly the same as the background cpm.

The amount of shear-induced 5-lipoxygenase products (LTB_4, 5-HETE) in sheared PMNL suspensions alone was much less than when supernatant of sheared PRP was present (data not shown). In fact, LTB_4 production under these conditions was negligible. Shear-induced 5-HETE production in the PMNL suspensions has also been quantitated using radioimmunoassay with labeled antibody purchased from Seragen. The formation of 5-HETE increased proportionally with the shear stress increase (data not shown). PMNLs and 5.5 μmol/L 1-^{14}C arachidonic acid were incubated with 10 μmol/L ionophore A23187 in the presence of sheared PRP supernatant. In this case, production of LTB_4 by PMNLs after shearing increased even more dramatically. It is noteworthy that 5-HETE production was increased and 15-HETE formation was decreased (Fig 10).

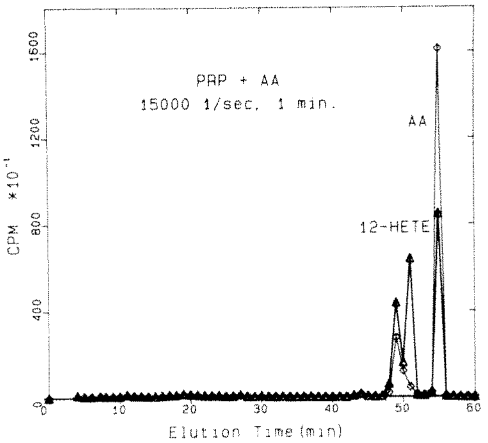

Fig 9. RP-HPLC chromatogram of the metabolites of arachidonic acid formed in PRP incubated with 5.5 μmol/L 1-^{14}C arachidonic acid. Control (◇) and after shearing at 150 dynes/cm^2 for one minute (△).

DISCUSSION

In this paper, we have shown that a substance(s) derived from platelet activation in a shear field may activate the C-5 lipoxygenase of human blood PMNLs in vitro. However, there is an activation (shearing) requirement for PMNL aggregation even though the cells have been incubated with supernatant plasma of sheared PRP (Fig 3B). PMNLs incubated with plasma alone show some shear-induced aggregation (Fig 3C). This may be due to the plasma protein binding and, to a lesser extent, viscosity changes. The difference between B and C in Fig 3 indicates that a substance(s) derived from shear activated platelets plays an active role in this PMNL aggregation.

Sheared platelets release ADP and serotonin, which are potent platelet-aggregating agents. However, 2 μmol/L ADP and 2 μmol/L serotonin do not cause PMNL aggregation (Fig 3D and E, respectively). Redl et al[26] recently demonstrated that platelets augment granulocyte aggregation by a serotonin and thromboxane A_2-independent mechanism, and it was not necessary for platelets to be intact for them to augment granulocyte aggregation. Indeed, platelet lysates and the supernatant fluids therefrom proved equally efficacious. NDGA (10 μmol/L) and U-60257 (10 μmol/L) totally suppressed the shear-induced PMNL aggregation to that level seen in a mixture of PMNL and PFP (Fig 4C and D, respectively). It is hypothesized that the platelet-derived PMNL activating substance may be 12-HPETE. Shear-induced aggregation of platelets produces the release of arachidonic acid from cellular phospholipids and the subsequent metabolism of the arachidonic acid by cyclo-oxygenase and lipoxygenase systems. It is interesting that in

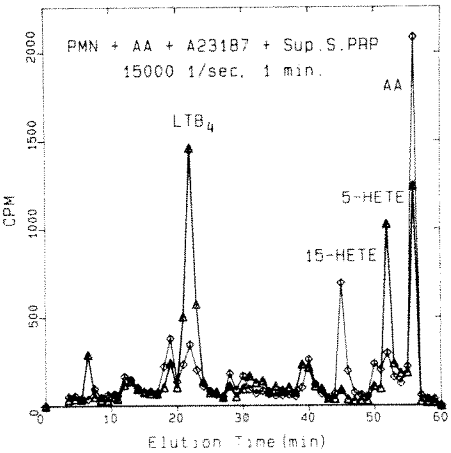

Fig 10. RP-HPLC chromatogram of the metabolites of arachidonic acid formed in human PMNLs incubated with the ionophore A23187 (10 μmol/L) and 5.5 μmol/L 1-^{14}C arachidonic acid in the presence of supernatant of sheared PRP. Control (◇) and after shearing at 150 dynes/cm^2 for one minute (△).

shear activation, a substantial portion of the free arachidonic acid is transformed by a lipoxygenase to 12-HPETE and, subsequently, 12-HETE (Fig 9). This 12-HPETE may activate the C-5 lipoxygenase in PMNLs and therefore lead to increased release of C-5 lipoxygenase products, such as 5-HETE and LTs. Figure 11 shows a hypothetical scheme of the platelet–PMNL interactions that may lead to increased release of leukocyte C-5 lipoxygenase products.

It has been shown that the C-15 lipoxygenase also interacts with the C-5 lipoxygenase to produce a (5S, 15S)-5,15-dihydroxy-6,8,11,13-eicosatetraenoic acid (5S, 15S diHETE).[10] The formation of the 5S, 12S diHETE and of the 5S, 15S diHETE reflects the interactions between lipoxygenase enzymes in different blood cells. Marcus et al[27] have shown a new metabolite of arachiconid acid, formed during interaction between thrombin- or collagen-stimulated platelets and unstimulated neutrophils. That was confirmed to be 12S, 20-dihydroxyeicosatetraenoic acid (12S, 20 diHETE). Their experiments showed that platelet stimuli known to occur in vivo might initiate metabolic interactions between different cell types by way of the arachidonic acid pathway. Leukotriene B_4 (LTB_4) is a potent chemotactic factor and induces PMNL aggregation. The stimulation of LT synthesis in human blood leukocytes by 12-HPETE has been observed.[10] Plasma protein binding in our system may stabilize 12-HPETE, prolonging its activity over that seen in buffers alone. LT biosynthesis requires enzymes that are distributed among different subcellular compartments, and it appears that their biosynthesis involves movement of intermediates between these compartments.[28] In the case of LTB_4 formation, the action of a soluble cytosolic hydrolase has been proposed to be the rate-limiting step.[17] Consequently, intermediate substrates such as 5-HPETE or LTA_4 must accumulate, decay by way of alternate enzymatic and nonenzymatic processes, or be released from cells, such as PMNLs. In the latter instance, a plasma enzyme capable of metabolizing extracellular LTA_4 to LTB_4 seems reasonable. In fact, recent studies suggest that an extracellular enzymatic transformation of LTA_4 into the potent chemotaxin LTB_4 may be involved.[29,30] Plasma enzymatic activity responsible for LTB_4 production may play a general role in modulating the inflammatory response.

The 5-lipoxygenase is present in PMNL in an inactive form and must be activated to catalyze the dioxygenation of arachidonic acid. Evidence that the lipoxygenase pathway might be involved in PMNL activation comes from the studies showing that rabbit exudate PMNLs are stimulated directly by exogenous arachidonic acid to release HETEs and LTB_4[4,14] and to aggregate.[31] In a recent study, it was shown that human PMNLs, isolated from normal individuals, are stimulated when given a combination of arachidonic acid and ethanol, which apparently activates the 5-lipoxygenase pathway for PMNLs. However, the addition of arachidonic acid alone to human blood PMNL suspensions does not induce significant synthesis of 5-lipoxygenase products.[4]

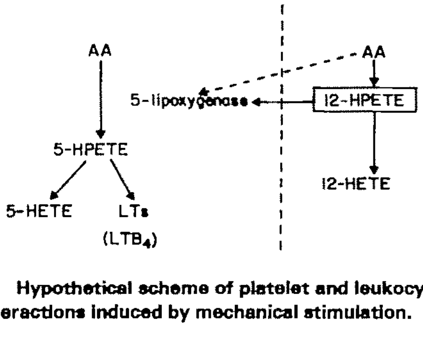

Fig 11. Hypothetical scheme of platelet and leukocyte lipoxygenase interactions induced by mechanical stimulation.

The divalent cation ionophore A23187 is known to be a potent activator of the synthesis of LTs. Its action probably involves the stimulation of Ca^{2+} flux and the subsequent activation of the Ca^{2+}-dependent 5-lipoxygenase and phospholipases. It thus appears that the release of arachidonic acid (after phospholipase stimulation) and the activation of the 5-lipoxygenase are prerequisites for the synthesis of 5-lipoxygenase products in human blood PMNLs. One possible mode of action of stress-induced mechanical activation is a membrane mechanical stretching induced increased calcium flux, leading to increased intracellular enzymatic activity. Also, Volpi et al[32] have shown that the addition of arachidonic acid to neutrophils will cause a rapid and significant increase in the permeability of the plasma membrane to calcium. This hypothesis is supported by the similarity of A23187-induced (Fig 1) and shear-induced (Fig 2) PMNL aggregation time course curves.

Quantitative confirmation of lipoxygenase involvement in the shear-induced aggregation process was obtained using RP-HPLC. The formation of LTB_4 was greatly increased after shearing PMNL in the presence of supernatant plasma from sheared platelets (Figs 7 and 10). When the leukocytes were stimulated both by ionophore A23187 and shearing, LTB_4 and 5-HETE production increased dramatically. However, preincubation of 10 μmol/L NDGA with PMNL suspensions totally suppressed the increment of LTB_4 formation after shearing (Fig 8). This again supports the hypothesis that these 5-lipoxygenase products induce PMNL aggregation.

Small amounts of diHETEs were detectable when PMNL suspensions were sheared in PFP or in buffers. Sheared platelets exhibited greatly increased synthesis of 12-HETE (Fig 9) with surprisingly little thromboxane B_2 production. This indicates that shear stress stimulation of platelets may produce quite different arachidonic acid metabolite than that seen with direct chemical stimuli, such as thrombin or the ionophore A23187. This platelet-derived 12-HETE (12-HPETE) may be the mediator that stimulates the 5-lipoxygenase activity in human PMNLs during stress-induced aggregation. The fact that preincubation of PRP with a 12-lipoxygenase inhibitor (NDGA, 10 μmol/L) before shearing blocked the effect of sheared-platelet supernatant on PMNL aggregation strengthens our hypothesis.

The platelet-PMNL ratio appears to be important (Fig 6). When the ratio is approximately the same as found under physiological conditions, the aggregation response of the PMNL is maximum. It is possible that, in addition to the platelet-PMNL ratio, the cell concentration in the incubation medium is an important parameter. This has been observed in studies examining the possibility of platelet-derived endoperoxides serving as substrates for endothelial cell prostacyclin synthase.[33]

In summary, our studies suggest important roles for the platelet and PMNL C-12 and C-5 lipoxygenases in shear-induced PMNL aggregation. These data support the concept of platelet–PMNL interactions in shear-induced PMNL aggregation and add new data concerning the potential role of release products from one cell type in modulating the biological and mechanical response of another blood cell.

CONCISE REPORT

Analysis of T-Cell Receptor Beta Chain (T_β) Gene Rearrangements Demonstrates the Monoclonal Nature of T-Cell Chronic Lymphoproliferative Disorders

By Robin Foa, Pier-Giuseppe Pelicci, Nicola Migone, Francesco Lauria, Giovanni Pizzolo, Frances Flug, Daniel M. Knowles II, and Riccardo Dalla-Favera

We investigated the rearrangement patterns of the gene coding for the beta chain of the T cell receptor (T_β) in 11 patients with T-cell derived chronic lymphoproliferative disorders, including T-cell prolymphocytic leukemia (T-PLL) and T-cell chronic lymphocytic leukemia (T-CLL). We found that all five cases of T-PLL, and five of six cases of T-CLL, displayed T_β-gene rearrangements, clearly establishing their monoclonal nature. Clonality could not be determined in one case of T-CLL where the T_β gene was found unrearranged. Our results demonstrate that the majority of cases of both clinically aggressive T-PLL and clinically indolent T-CLL are monoclonal. These results suggest that the analysis of T_β gene rearrangements represents a valid tool for the differential diagnosis and clinical monitoring of T-cell derived chronic lymphoproliferative diseases.

© 1986 by Grune & Stratton, Inc.

T-CELL chronic lymphoproliferative disorders are well recognized clinicopathologic diseases, which include T-cell prolymphocytic leukemia (T-PLL) and T-cell chronic lymphocytic leukemia (T-CLL). T-PLL is usually characterized by clinical features suggesting a malignant process, ie, a high WBC count, marked splenomegaly, an aggressive clinical course and a limited therapeutic response.[1] T-CLL, including large granular lymphocyte (LGL) proliferations (T_γ-lymphoproliferative disease, T_γ-LPD),[2] are generally characterized by a relatively low WBC count, an indolent, nonprogressive clinical course and prolonged survival.[2,3] The benign clinical course of many cases of T-CLL has led some authors[2,4] to question their neoplastic nature and to recommend the term chronic T-cell lymphocytosis[4] unless disease progression is demonstrable. Difficulty in determining the neoplastic or the reactive nature of these cases has stemmed from the lack of an adequate marker of clonality for T-cell populations.

Recently, DNA sequences coding for the beta chain of the T-cell receptor (T_β) have been isolated. It has been shown that the T_β locus undergoes structural rearrangements that precede and are necessary for T_β gene expression in T-cells,[5-8] analogous to immunoglobulin gene rearrangements in B-cells.[9,10] We and others have demonstrated that the patterns of T_β gene rearrangement, identified by Southern blot hybridization analysis using T_β gene probes,[11-13] can be used to identify the mono- or polyclonality of a given T-cell population.[12] We used this immunogenotypic approach, in the studies described here, to demonstrate that the vast majority of T-cell chronic lymphoproliferative disorders, including clinically aggressive T-PLL and clinically indolent T-CLL, are monoclonal T-cell proliferations.

PATIENTS AND METHODS

Patients and diagnosis. We studied six cases of T-CLL and five cases of T-PLL. Diagnoses were established by conventional clinical, morphological, and phenotypic criteria. All six patients with T-CLL exhibited a benign clinical course and a moderate lymphocytosis. The cells in five patients (Table 1, cases 2 through 6) displayed typical LGL morphology, ie, abundant azurophilic granular rich cytoplasm, and absent nucleoli. The cells in one patient (Table 1, case 1) were small, mature appearing lymphocytes, without nucleoli and without LGL morphology. All five patients with T-PLL exhibited an aggressive clinical course and a lymphocytosis of intermediate sized cells with moderately basophilic cytoplasm, vesicular nuclei, and prominent nucleoli.

Immunophenotypic analysis. Sheep erythrocyte (E) rosette formation was assayed with Vibrio Cholera neuraminidase-treated sheep erythrocytes. T-cell associated antigen expression was determined by indirect immunofluorescence using murine monoclonal antibodies OKT3, OKT4, OKT6, OKT8, OKT11, and Leu7.[14]

Cytotoxicity assays. NK activity was measured using K562 leukemia cells as target cells, at effector to target cell (E:T) ratios ranging from 25:1 to 100:1, in a four hour ^{51}Cr release assay. For ADCC, ^{51}Cr-labelled TLX9 lymphoma cells, sensitized with rabbit antibody, were used as targets in a four hour test.

Gene rearrangement studies. DNA purification was performed by cell lysis, proteinase K digestion, extraction with phenol/chloroform and precipitation with ethanol.[15] Fifteen micrograms of DNA extracted from each sample were digested with the appropriate restriction endonuclease, electrophoresed in a 0.8% agarose gel, denatured, neutralized, and transferred to a nitrocellulose filter as described.[15] The probe used in this study is represented by a 440 base pair (bp) *Hin*cII fragment representative of the Constant region of the T_β gene ($T_\beta C$). The original clone and the generation of the probes have been described.[6,12]

RESULTS

In general, these 11 cases displayed the typical clinical and phenotypic characteristics of T-CLL or T-PLL (Table 1). In some cases, the cells displayed a relatively infrequent phenotype, the simultaneous expression of T4 and T8. This phenotype is exceptional in T-CLL[2] and infrequent in T-PLL.[16]

We previously demonstrated that the analysis of T_β gene rearrangements by Southern blot hybridization using T_β probes, allows the definition of the lineage, ie, T-cell, and the mono- or polyclonal nature of a given lymphoid cell population.[12] Figure 1 (lanes A) illustrates the pattern of hybridization bands obtained when human DNA from a non-T-cell population is digested with *Eco*RI or *Bam*HI and hybridized to the T_βC probe. The same analysis, performed on DNA obtained from a polyclonal T-cell population, represented by either normal thymocytes or peripheral blood T-lymphocytes, shows the biallelic deletion of the 12.0 kb band upon digestion with *Eco*R1 and a conserved germline pattern upon digestion with *Bam*HI (Fig 1, lanes B). In monoclonal T-cell populations, the restriction pattern of the gene is characterized by the same *Eco*RI band deletion and in addition, by the presence of one or more rearranged band(s), which can be detected by digestion with at least one restriction enzyme (see ref. 12 and below).

We analyzed the six cases of T-CLL and five cases of T-PLL based upon this scheme. Southern blot analysis demonstrated the presence of T_β gene rearrangements in all five cases of T-PLL and in five of six cases of T-CLL (Table 1). All of the cases but one displayed the disappearance of the 12.0 kb *Eco*RI band and the appearance of new hybridization bands upon DNA digestion with *Eco*RI and/or *Bam*HI (or *Hind*III, not shown) restriction enzymes. Three cases displaying T_β gene rearrangements are illustrated in Fig 1. Cases 3 and 11 showed the appearance of rearranged bands upon DNA digestion with both *Eco*RI and *Bam*HI. In Case 3, the absence of the *Eco*RI and *Bam*HI germline fragments together with the appearance of a single rearranged band, suggests the deletion of one allele of the T_β gene and the rearrangement of the other. A rearranged band in Case 10 is apparent only upon DNA digestion with *Bam*HI restriction enzyme. The single case without rearranged bands also showed conservation of the *Eco*RI 12.0 kb band (see 6 in Fig 1), indicating that the T_β gene is unrearranged in these cells. This finding was confirmed by digestion of the same DNA with *Bam*HI (Fig 1, Lane 6) and *Hind*III (not shown) restriction enzymes. Analysis of the immunoglobulin heavy chain locus showed a germline configuration in all 11

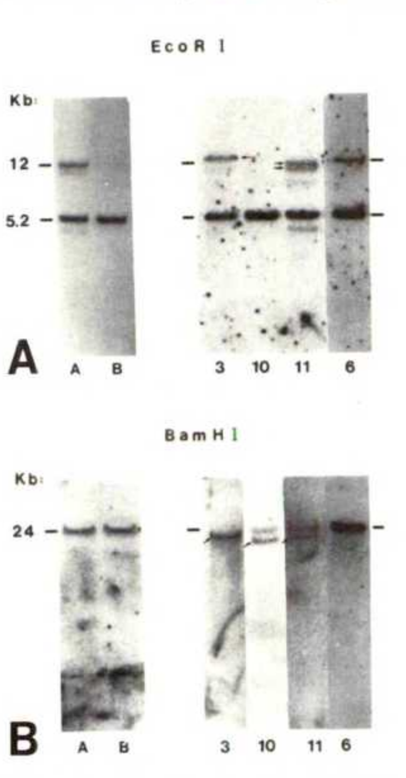

Fig 1. Autoradiographs showing representative results of analysis of T_β gene rearrangements in chronic T-cell derived lymphoproliferative disorders. (A) DNAs from normal human fibroblasts, (B) normal human peripheral blood T-lymphocytes, and from pathologic samples (Cases 3, 6, 10, 11) (see Table 1) were digested with *Eco*RI and *Bam*HI as indicated and hybridized to T_βC probe. Dashes indicate germline bands, arrows indicate rearranged bands.

cases (data not shown). Thus, our data indicate that ten of the 11 T-cell chronic lymphoproliferative disorders are monoclonal T-cell proliferations, since the cells display clonal T_β gene rearrangements. Clonality could not be determined by this approach in one case of T-CLL, since the T_β gene was found to be unrearranged.

DISCUSSION

This study sought to determine the mono- or the polyclonality of T-cell chronic lymphoproliferative disorders, including T-PLL and T-CLL. In contrast with most other neoplasms, the monoclonality of some of these cases, particularly T-CLL, cannot be assumed or easily established in view of: (1) their nonaggressive, clinical behavior; (2) the lack of cytogenetic markers to confirm both their clonality and, by analogy with other neoplasms, their malignancy; and (3) the lack of clearly identifiable morphologic or immunophenotypic features to distinguish them from their normal, benign counterparts.

The studies presented here demonstrate that the vast majority of T-cell chronic lymphoproliferative disorders are monoclonal. The monoclonal and probable malignant nature of T-PLL is strongly suggested by its typical aggressive clinical course. However, the monoclonal nature of T-CLL was also established in five of six cases. The latter cases display a nonaggressive clinical course and immunophenotypic features, which pose reasonable doubts in terms of the differential diagnosis between a benign chronic lymphocytosis and a true lymphoid malignancy. For instance, Case 2 displayed a particularly benign clinical course during three years of follow-up. We also demonstrated that some chronic lymphoid proliferations which display a mixed T4/T8 phenotype are monoclonal. These cases may be more frequent than previously reported,[16] and may have often been inappropriately classified as chronic T-cell lymphocytoses by immunophenotypic analysis.

One case of T-CLL exhibited an unrearranged T_β gene configuration. The cells from this case exhibited LGL morphology and NK function, although their T3- T4- T8- phenotype (Table 1) differed from the other cases of T-CLL displaying LGL features. These observations suggest that LGL-derived T-CLLs are immunogenotypically and immunophenotypically heterogeneous. They may be derived from more than one lineage and/or different stages of differentiation. This heterogeneity may reflect the heterogeneity of the normal LGL population and is consistent with our preliminary observations that T_β gene rearrangement and expression is found in only a subpopulation of normal peripheral blood LGL cells (Pelicci PG et al, manuscript in preparation). With respect to the present study, we conclude that the large category of T-CLL may include a distinct subset of cases with LGL morphology, the monoclonal nature of which remains to be established.

Establishing the monoclonal nature of these cases bears important implications for their differential diagnosis, prognosis, and therapeutic management. First, it is important to note that the monoclonality of these diseases does not necessarily imply their complete malignancy. At least some of these cases may represent early, yet persisting stages of a multi-step leukemogenic process. The existence of cases that undergo a progressive change in their clinical course switching toward a more aggressive and malignant phenotype[2] supports this notion. Analysis of T_β gene rearrangements in longitudinal studies is likely to be useful in determining the derivation of these more malignant clones, by comparing their genotype and phenotype with those cells of earlier stages of the disease. The determination of clonality by T_β gene rearrangement analysis may be of significant diagnostic and prognostic value. Although our study suggests that even the most clinically chronic T-cell proliferations are of monoclonal origin, immunogenotypic analysis may still be needed to clarify difficult diagnostic situations. Once the determination of monoclonality has been made, the immunogenotypic marker would appear to represent a convenient tool with which to follow the biologic behavior and the therapeutic response of the pathologic clone, thus allowing improved monitoring of the patients' clinical course.

ACKNOWLEDGEMENT

We thank Dr Tak Mak for providing the T_β probe, Michel Brathwaite and Angela Ubriaco for excellent technical assistance, and Diane Nazario and Margaret Walden for preparing the manuscript.

CORRESPONDENCE

EPSTEIN-BARR GENOMES

To the Editor:

In the recent article, "Epstein-Barr Genomes are Restricted to Secondary Neoplastic Cells Following Bone Marrow Transplantation," by William H. Schubach, George Miller and E. Donnall Thomas,[1] the authors concluded that marrow transplant patients acquire Epstein-Barr virus (EBV) genomes infrequently in engrafted normal lymphocytes. From the title of Table 1 it is presumed that DNA samples were from peripheral blood mononuclear cells and that EBV genome was found in five patients. However, in the results section it is stated that the EBV genomes were contained in the cells of secondary lymphoid neoplasms. Did both the peripheral blood mononuclear cells as well as the neoplastic tumor cells contain EBV? If in these EBV associated tumor patients the peripheral blood mononuclear cells were found not to contain EBV, then perhaps the possibility exists that circulating mononuclear cells may not be a sensitive marker of the acquisition of EBV. Perhaps in the posttransplant setting, tissue such as lymph nodes or spleen might contain EBV genomes since these are sites for the development of secondary lymphoid neoplasms.[2] Did the authors study any other tissue besides peripheral blood mononuclear cells for EBV genome?

To the Editor:

Dr Wolff asks the important question whether we sought EBV genomes in B cell repositories such as lymph nodes or spleen from patients not suffering from secondary lymphomas. For a variety of practical reasons this could not be done in the reported study. We chose to look for the acquisition of EBV genomes in bone marrow and peripheral blood at various times after engraftment. Aside from considerations of feasibility and convenience, this seemed a likely tissue to examine, since repopulation of marrow by B cells[1,2] of donor origin[3] has been documented by others. In these same studies, repopulating B cells were transformed in vitro by EBV. In our study we did not examine peripheral blood mononuclear cells of patients suffering secondary lymphomas. The EBV genomes found in these cases were detected in tumor samples, the only tissues examined from these patients. We do not know whether lymphocytes in other tissues contained EBV and we agree that such a study would be informative.

EFFECT OF ALPHA AND GAMMA INTERFERON ON CFU-GM

To the Editor:

The conclusion of Rigby et al[1] that both alpha and gamma recombinant interferons inhibit granulocyte/monocyte colony-forming cells (CFU-GM) growth in a dose-dependent manner, a conclusion already reached by several groups,[2-4] is probably not compromised by the experimental approach used. However, for the other conclusions, it must be pointed out that the results were obtained in a culture system containing, as the source of colony stimulating activity, leukocyte-conditioned medium stimulated by 10% phytohemagglutinin (PHA) and normal blood mononuclear cells which had not been depleted of T lymphocytes. In a study designed to explore the effect of interferons on normal and leukemic cells as well, this type of stimulation of CFU-GM is open to criticism.

First, previous studies have shown that lymphocytes stimulated by PHA produce, in vitro and in vivo, sufficient amounts of gamma interferon to inhibit CFU-GM growth.[5,6] Thus, to conclude that gamma interferon is 10 to 100 times more cytotoxic to CFU-GM than alpha interferon, T lymphocyte-depleted blood cells should have been used instead of the whole mononuclear fraction to compare the normal and leukemic progenitors.

Second, PHA present in the culture medium is known to stimulate the growth of T lymphocyte colonies. Therefore, the observed effect of both alpha and gamma interferons might not be restricted to the CFU-GM but could instead reflect the inhibitory activity exerted on both CFU-GM and T lymphocyte colonies, since laboratory and clinical studies suggest that interferons inhibit T lymphocyte proliferation.[7,8] This is also true when the authors compare normal CFU-GM and blast progenitor cells. Thus, their conclusion that normal and leukemic myeloid progenitors are equally inhibited by the interferons appears debatable to us.

In our hands, with human placental conditioned medium as the colony stimulating activity and T-depleted mononuclear cells from leukemic patients stimulated by 10% PHA-LCM, we have observed in a limited number of cases (14 normal subjects, and three patients with acute nonlymphoblastic leukemic) that leukemic progenitors were less sensitive than normal CFU-GM to alpha and gamma recombinant interferon (Boehringer Ingelheim).

To the Editor:

We are appreciative of the thoughtful comments by Delforge et al. With regard to their first point, it is possible that gamma, as well as alpha, interferon was present in our lymphocyte conditioned medium. Nevertheless, it is unlikely that significant differential effects resulted as linear dose-response curves were observed with each interferon. Furthermore, Broxmeyer et al reported similar data on day 14 granulocyte/monocyte colony-forming cells (CFU-GM) using cell line giant cell tumor (GCT) conditioned medium as a source of colony-stimulating activity, thus lacking any potential interferon contamination.[1]

Second, the colonies in our cultures were clearly CFU-GM in morphology and we have confirmed this through Wright-Giemsa staining. Leukemic colonies from donor 1 did not display typical CFU-GM morphology but, instead, were less well differentiated. Significant lymphocyte colony contamination seemed a most unlikely possibility, given that 100% of the patient's leukocytes were blasts.

Finally, we look forward to the evolution and publication of their preliminary studies on leukemic progenitor cells. Potential differences between their observations and ours may result as a consequence of their use of two sources of colony stimulating activity in their cultures, as well as the innate variability of myeloid leukemia cells.

ANTI-COMMON ACUTE LYMPHOBLASTIC LEUKEMIA ANTIBODY (CALLA) (J5) REACTIVITY BY SMALL CELL LUNG CANCER (SCLC) CELLS

To the Editor:

In a recent article in *Blood*, Bunn et al[1] reported the expression of lymphoreticular antigens (Leu-7, Leu-11, OKT10, OKM1, Leu-M1, Leu-M2, OKT9) as detected by immunofluorescence analysis on cell lines deriving from oat cell carcinoma of the lung. In another article in *Science*, Ruff and Pert[2] describe the presence of OKM1 antigen on two SCLC cell lines and four SCLC autopsy specimens; they propose that the observed expression of OKM1 by SCLC may indicate the origin of SCLC from bone marrow macrophages; in contrast to the proposed theory, Gazdar et al[3] point out that shared antigenicity does not necessarily indicate common lineage or embryologic origin.

We are reporting here for the first time the binding of the J5 (anti-CALLA)[4] monoclonal antibody to SCLC cells deriving from a bone marrow specimen of a patient with lung, bone, and bone marrow involvement by SCLC at an advanced disease stage. Flow cytometric analysis of the SCLC cells stained by an indirect immunofluorescent technique showed that 16% of such cells were J5 positive. In addition, 41% of the small cells were Leu-M1 positive and 22% were Leu-9 positive. The Ia (HLA-DR related) antigen as well as kappa and lambda chains and the MO_2 antigen were not detected on the cell surface. Leukemic cells were not observed in the bone marrow smear or on biopsy specimen.

The J5 monoclonal antibody has also been reported to react with adult and fetal renal proximal tubule cells, adult breast myoepithelium[5] as well as common bile duct cells. Although CALLA antigenic expressions occur in cultured marrow and skin fibroblasts[6] there is not enough evidence to prove that SCLC derives from such ancestor cells. Mature granulocytes also express CALLA.[6] The biologic significance of such expression by normal or cultured cells remains to be proven.

We agree with Gadzar et al that caution should be applied in interpreting the shared reactivity of various tissues with white cell antibodies as adequate and as the sole indicator for a common embryologic origin. Expressions of such antigens by malignant cells may indicate gene dysregulation rather than a common origin, especially in highly undifferentiated tumors like SCLC.

To the Editor:

We agree with the comments of Drs Efremidis and Bekesi regarding the interpretation of antigens shared by many tissues of diverse embryonic origin. We have found CALLA expressed on three of 13 small cell lines we have evaluated. The expression was noted in a minority of cells (38% to 50%) in the lines. We have previously reported low or absent expression of HLA class I antigens in small cell carcinoma.[1] In our experience, HLA-DR-related antigens are more normally expressed, but your findings are of interest. We continue to believe that small cell lung cancer is an epithelial tumor with neuroendocrine properties.[2,3]

MYELOFIBROSIS WITH MYELOID METAPLASIA

To the Editor:

I have read with interest the paper of Wolf and Neiman entitled "Myelofibrosis with myeloid metaplasia: Pathophysiologic implications of the correlation between bone marrow changes and progression of splenomegaly" in the April issue of BLOOD (65:803, 1985). We recently had two boys (14 and 9 years old) with agnogenic myeloid metaplasia; in one this patchy appearance of stromal proliferation was well shown with augmented megakaryocytes by chance, supporting the authors' finding.[1]

Although the authors mentioned infection, metastatic carcinoma, exposure to myelotoxins and other hematologic disorders as a cause of secondary myelofibrosis, they did not refer to rickets, vitamin D deficiency,[2] or chronic renal failure.[3] I would like to bring into focus that increased bone marrow collagen, megakaryocytes and stromal hyperplasia all could be related to vitamin D metabolytes and/or increased parathormone level.[4]

ANNOUNCEMENTS

CLINICAL HEMATOLOGY AND ONCOLOGY: 1986

February 17–19, 1986
Vacation Village Resort, San Diego, Calif
Sponsored by Scripps Clinic and Research Foundation, La Jolla, Calif.
Ernest Beutler, MD, Program Chairman

This course is designed for hematologists, oncologists, internists, pediatricians, and pathologists interested in the diagnosis and management of hematologic and oncologic disorders. An outstanding faculty from across the continent has been assembled to discuss various aspects of these fields, to aid clinicians in sorting out the important from the trivial, and to help identify those recent advances which will withstand the test of time.

For further information and application forms, contact: Bonny Mower, Department of Academic Affairs, Box 400S, Scripps Clinic and Research Foundation, 10666 N Torrey Pines Rd, La Jolla, CA 92037. (619) 457-8556.

The members of the International Society of Blood Transfusion (ISBT) Working Party on Terminology for Red Cell Surface Antigens wish to bring their Munich Report, (*Vox Sang* 49:171–175, 1985), to the attention of the readership of *Blood*.

The Working Party was established to promote uniformity and nonduplication in alphabetical nomenclature for red cell surface antigens and to provide a standard numerical terminology. The report contains listings of ISBT-approved designations and guidelines for the designations of "new" antigens. Interested persons may wish to contact local committee members: *Australia* (S. Young); *Canada* (M. Crookston, M. Lewis, B.P.L. Moore); *Denmark* (J. Jørgensen), *England* (D.J. Anstee, G.W.G. Bird, M. Contreras, G. Daniels, C.M. Giles, A. Lubenko, P.A. Tippett); *Finland* (H. Nevanlinna, P. Sistonen), *France* (Ch. Salmon); *Germany* (W. Dahr, S. Seidl); *Holland* (C.P. Engelfriet); *Japan* (Y. Okubo, J. Yasuda); *New Zealand* (P. Booth, G. Woodfield); *Norway* (L. Kornstad, R. Nordhagen); *USA* (F.H. Allen, Jr, E. Brodheim, P.D. Issitt, W.L. Marsh, P. Morel, J.J. Moulds, R.E. Rosenfield, B. Sabo, R.H. Walker).

The Neurovascular Society of North America/Society for Neurovascular Surgery requests abstracts dealing with acute or chronic neurologic manifestations due to a neurovascular, hemodynamic, or hematological mechanism. Any clinical aspect of a problem may be discussed. The NVSNA/SNVS meeting will be held on April 17–19, 1986 in Chicago. Abstract Deadline: January 15, 1986.

For further information contact Andrew L. Carney MD: call 1 (312) 482-3950 or write NVSNA/SNVS, Box 679, Oak Park, IL 60302.

HYBRIDOMAS IN BIOTECHNOLOGY AND MEDICINE

March 3–7, 1986
Boston, Mass.

Organizers: T.A. Springer, PhD, S.J. Burakoff, MD, E.L. Reinherz, MD
Sponsored by
Dana-Farber Cancer Institute
Harvard Medical School

This course is designed for scientific investigators interested in the latest innovations and implications of immunology and hybridoma technology. Monoclonal antibodies and T cell lines are extraordinarily specific and powerful reagents which have opened up new avenues of investigation in clinical medicine, biotechnology, and diverse biological disciplines. A distinguished faculty will review the relevant basic immunology and highlight the major advances achieved by application of this new technology. A comprehensive syllabus including selected methods protocols will be provided.

Ths course is divided into five sections: (1) Antibody diversity and monoclonal antibodies; (2) Applications of monoclonal antibodies in basic biomedical research; (3) Monoclonal antibodies in diagnosis and therapy; (4) Uses of antibodies in recombinant DNA technology; and (5) T cell clones, hybridomas, and their products.

To register and for additional information, write to Harvard Medical School, Department of Continuing Education, Boston, MA 02115 or call (617) 732-1525 from 10 AM to 4 PM.

Blood, Vol 67, No 1 (January), 1986: pp 254–256

TRANSPLANTATION SYMPOSIUM

April 28–30, 1986
Washington, DC

The American Red Cross announces its 1986 Annual Symposium, "Transplantation: Progress and Prospects." Emphasis will be on graft rejection and its prevention. Specific topic areas will be: Immunology of Graft Rejection— biology and function of T cells, role of humoral antibodies, review of experimental studies; Prevention of Rejection by Treatment of the Graft—class II antigen depletion, irradiation, T cell depletion, and immunosuppression in graft-*v*-host disease; Prevention of Rejection by Treatment of the Recipient—transfusion therapy, monoclonal antibodies, total lymphoid irradiation, and cyclosporine; Other Critical Aspects of Transplantation— reperfusion injury, organ perfusion, organ cryopreservation.

Attendance will be limited to 280. To receive further mailings, registration, and hotel information, write to Harold T. Meryman, MD, Biomedical Research and Development Laboratory, American Red Cross, 9312 Old Georgetown Rd, Bethesda, MD 20814.

INTERNATIONAL CONFERENCE ON AIDS

June 23–25, 1986
Palais des Congres, Paris

The congress will cover all aspects of contemporary research: virology, molecular biology, animal models, immunology, clinical aspects, pediatric AIDS, African AIDS, therapy, diagnostics, serology, epidemiology, public health, and psychosocial implications. Deadline for abstracts is February 1, 1986. For all information please contact Dr Jean-Claude Gluckman, Faculté de Médecine Pitié-Salpêtrière, 91 Boulevard de l'Hôpital, 75634 Paris Cedex 13, France. Telephone: (1) 45 70 27 02.

RESEARCH TRAINEE POSITION AVAILABLE

Research trainee position available for MD training in hematology/oncology and bone marrow transplantation (BMT). Research project in leukemia, BMT, or cell metabolism. Apply to Dr B.A. Cooper, Room A2.02, Royal Victoria Hospital, Montreal, Quebec H3A 1A1, Canada.

17th INTERNATIONAL CONGRESS OF THE WORLD FEDERATION OF HEMOPHILIA

June 8–13, 1986
Universita Statale, Milan, Italy

The main theme of the Congress is *Progress in Hemophilia Through Biotechnology.* Main symposia are: The use of gene probes for prenatal diagnosis and carrier detection; production of clotting factors by biotechnologies; clinical trials of virus-inactivated concentrates; special diagnostic and clinical problems in hemophilia; the acquired immunodeficiency syndrome in 1986, an update; von Willebrand's disease; and the dentist and hemophilia.

Free communications and posters: Deadline for abstract presentation: Jan 31, 1986.

Scientific Secretariat: P.M. Mannucci, Via Pace 9, 20122 Milano, Italy. Telex: 315469 MGRMIL I.

SECOND ANNUAL HEMATOLOGY-ONCOLOGY SYMPOSIUM

Amelia Island, Florida
April 4–6, 1986

A conference designed for the practicing hematologist/oncologist. Up-to-date information with practical application and quality teaching.

Course Directors: Craig S. Kitchens, M.D. Warren A. Ross, M.D.
Guest Faculty: Victor J. Marder, M.D. Howard Ozar, M.D.
Special Guest & Speaker: Eugene A. Stead, M.D.
For further information contact: Craig S. Kitchens, PO Box 2715, Gainesville, FL 32602

SEMINARS IN HEMATOLOGY

Editors

Peter A. Miescher, M.D., and
Ernst R. Jaffé, M.D.

Volume 23, 1986
Published quarterly, approx. 310 pages per year
Annual subscription rate, U.S.A. and Canada:
$52.00 individuals/$68.00 institutions
(All other countries: $75.00)
ISSN: 0037-1963

A topical journal on subjects of current importance in clinical hematology and related fields, **Seminars in Hematology** is devoted to making the present status of such topics and the results of new investigations readily available to the practicing physician. It is of special interest to hematologists, oncologists, internal medicine specialists, blood bankers, and specialists in thrombosis and hemostasis.

SCHEDULED TOPICS, VOLUME 23, 1986:

JANUARY — PLATELETS AND MEGAKARYOCYTES IV
Guest Editors: *Paul K. Schick, M.D., and Helge Stormorken, M.D.*

APRIL — PLATELETS AND MEGAKARYOCYTES V

Aggressive antibody protection against overwhelming infection for the immune-compromised patient
IMMUNE DEFENSE

NOW INDICATED FOR ITP

GAMIMUNE®

Immune Globulin Intravenous
5% (in 10% maltose)

The original IGIV... and still the clinical standard

The only IGIV proven by over three years of successful clinical experience in the United States.
Safe and effective use with more than 200,000 infusions has established GAMIMUNE as the IGIV of choice for patients with impaired humoral immune response who require rapid, broad-spectrum antibody protection.

The only ready-to-infuse, liquid IGIV.
The superior, patented GAMIMUNE formulation offers a significant advantage in IGIV therapy. Unlike lyophilized IGIV products, which can take up to 20 minutes for reconstitution, and which must be used immediately thereafter, GAMIMUNE is premixed, premeasured and can be stored under stated conditions for up to two years without increasing the risk of anticomplementary aggregate formation.

Speed...spectrum...and safety.
Infusion with GAMIMUNE rapidly provides high titers of antibody specific to a wide range of commonly occurring bacterial, viral and fungal pathogens—safely and with little or no patient discomfort. An unmatched, three-year safety record confirms: GAMIMUNE carries virtually no risk of serious anticomplementary side effects.[1,2] And, GAMIMUNE meets or exceeds all WHO standards for IGIV preparation.

Unsurpassed IGIV therapeutic efficacy.
The integrity of IgG molecules in GAMIMUNE is preserved in the reduction and alkylation process; antibodies remain functionally complete, possessing the full biologic activity of native immunoglobulin.[3,4,5]

FROM WITHIN

GAMIMUNE®

Immune Globulin Intravenous, 5% (In 10% maltose)

DESCRIPTION

Immune Globulin Intravenous, 5% in 10% Maltose (IGIV, 5% Maltose)-Gamimune® is a sterile 5 ± 1% solution of human protein stabilized with 10 ± 2% maltose; it contains no preservatives. The immunoglobulin is selectively reduced under controlled conditions using dithiothreitol and alkylated with iodoacetamide to render it suitable for intravenous administration. Each 10 mL contains approximately 500 mg of protein, not less than 90% of which is immunoglobulin. Thus, there are approximately 450 mg of immunoglobulin in each 10 mL of IGIV, 5% Maltose. The pH is 5.25 ± 0.25. The calculated osmolality is 327 milliosmoles per kilogram of solvent (water) and the calculated osmolarity is 292 milliosmoles per liter of solution. The product is prepared by cold alcohol fractionation from large pools of human venous plasma. Each individual unit of plasma has been tested and found nonreactive for hepatitis B surface antigen (HBsAg) using a test with third-generation sensitivity.

CLINICAL PHARMACOLOGY

Gamimune supplies IgG antibodies for prevention or attenuation of infectious diseases. The half-life of Gamimune is approximately three weeks but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immunoglobulin administered per dose is important in determining the frequency of administration of the drug for each patient.

While intravenous immunoglobulin has been shown to be effective in some cases of idiopathic thrombocytopenic purpura (ITP) (see Indications and Usage), the mechanism of action in ITP has not been fully elucidated.

Maltose is added to the solution in a 10% concentration for stabilization of the protein. A comparative clinical study of IGIV with and without maltose showed the incidence of adverse effects was significantly less with the maltose-containing preparation.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well and no adverse effects were observed at a rate of 0.25 g maltose/kg per hour. In safety studies conducted by Cutter Laboratories, infusions of 10% maltose administered at 0.27 to 0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous infusions of maltose, maltose was detected in the peripheral blood, and there was a dose dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were tolerated without significant adverse effects.

Since one milliliter of Immune Globulin Intravenous, 5% in 10% Maltose (IGIV, 5% Maltose)-Gamimune® contains 0.1 g of maltose, the recommended dose of Gamimune (0.1 g to 0.4 g per kilogram body weight) would result in the patient receiving a total of 0.2 g to 0.8 g maltose per kilogram body weight given over several hours. These amounts are within those levels tolerated in the Cutter safety studies cited above.

INDICATIONS AND USAGE

Immunodeficiency Gamimune is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune may be preferred to that of intramuscular immunoglobulin preparations especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., x-linked agammaglobulinemia), common variable hypogammaglobulinemia, x-linked immunodeficiency with hyper IgM, and combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura Some children and adults with ITP have shown an increase (albeit temporary) in platelet counts upon administration of Gamimune. Therefore administration of Gamimune should be considered in situations that require a rapid, temporary rise in the platelet count, for example, prior to surgery or to control excessive bleeding. However, it should be noted that not all patients will respond. Even in those patients who do respond, this treatment should not be considered to be curative.

CONTRAINDICATIONS

Immune Globulin Intravenous, 5% in 10% Maltose (IGIV, 5% Maltose)-Gamimune® is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Serum Globulin (Human). Individuals with selective IgA deficiencies who have known anti IgA antibody should not receive IGIV, 5% Maltose since these patients may experience severe anaphylactic reactions to even small amounts of immune globulin preparations.

WARNINGS

IGIV, 5% Maltose should be administered only intravenously as the intramuscular route has not yet been evaluated.

> IGIV, 5% Maltose can, on occasion, cause a precipitous fall in blood pressure and the clinical picture of anaphylaxis even when the patient is not known to be sensitive to immune globulin preparations. These reactions appear to be related to the rate of infusion. Accordingly, the infusion rate given under Dosage and Administration should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for treatment of any acute anaphylactoid reaction.

PRECAUTIONS

General Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid.

Drug Interactions If dilution is required Gamimune may be diluted with 5% dextrose. No other drug interactions or compatibilities have been evaluated. It is recommended that the infusion of Gamimune be given via separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C Animal reproduction studies have not been conducted with Immune Globulin Intravenous, 5% in 10% Maltose (IGIV, 5% Maltose)-Gamimune®. It is also not known whether Gamimune can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune should be given to a pregnant woman only if clearly needed.

Pediatric Use High dose administration of Gamimune in children with idiopathic thrombocytopenic purpura (ITP) did not reveal any adverse effects specific to the pediatric age group.

ADVERSE REACTIONS

In a small safety study of Gamimune in ten patients with primary immunodeficiency diseases, who received a total of 28 infusions at a dose of 400 mL per kg body weight, there were no adverse reactions reported during any of the infusions. Post infusion, three patients reported adverse effects "possibly" or "definitely" related to the IGIV infusion; two patients experienced post infusion headache, and one had a flu-like syndrome consisting of joint pain, red eyes, and fatigue following the infusion.

During additional investigational studies, 17 other patients with idiopathic thrombocytopenic purpura (ITP) received a total of 148 infusions of Gamimune. Most of these infusions were at doses of 400 mg/kg body weight for 5 consecutive days; however, some patients received either 400 mg/kg or 800 mg/kg body weight as a single infusion intermittently. In these studies, adverse reactions were reported in 17 of 148 (11.5%) infusions of Gamimune. Headache, generally mild, was the most common symptom noted, occurring during or following 8% of infusions. Other less frequently reported symptoms included emesis, chills, fever, chest tightness, and nausea. With rare exceptions, symptoms were either mild or moderate in degree.

Potential reactions with administration of intravenous gamma globulins may also include anxiety, flushing, chills, wheezing, abdominal cramps, back pain, myalgia, arthralgia, malaise and dizziness; rash has been reported only rarely. These reactions tend to be related to the rate of infusion; their management is described under Dosage and Administration.

True anaphylactic reactions to IGIV, 5% Maltose may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immune serum globulin, but some patients may tolerate cautiously administered IGIV without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immune globulin.

DOSAGE AND ADMINISTRATION

Prophylaxis of Immunodeficiency Syndromes: The usual dose of Gamimune for prophylaxis in immunodeficiency syndromes is 100 mg/kg body weight (i.e., 2 mL/kg body weight) administered once a month by intravenous infusion. If the clinical response is inadequate or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be increased to 200 mg/kg body weight (i.e., 4 mL/kg body weight) or the infusion may be repeated more frequently than once a month.

Therapy of Idiopathic Thrombocytopenic Purpura (ITP): The recommended dosage of Gamimune for therapy of ITP is 400 mg/kg of body weight (i.e., 8 mL/kg body weight) on five consecutive days.

Administration: Recent investigations confirm that Gamimune is well tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune be infused, by itself, at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes. If the patient does not experience any discomfort, the rate may be gradually increased to between 0.02 and 0.04 mL/kg body weight per minute. If side effects occur, the rate should be reduced or the infusion interrupted until the symptoms subside. The infusion may then be resumed at a rate which is tolerated by the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Twenty years ago, leukemia* killed enough people to fill the Houston Astrodome.

Twenty years ago, leukemia was a mysterious disease. Little was known about the cause. Less was known about the cure.

But since then, the Leukemia Society of America has funded 32 million dollars of medical research in an all-out effort to find a cure.

Today, more and more people with leukemia are surviving. Living normal lives. But the Leukemia Society won't be satisfied till this killer is stopped for good.

For more information, including the free booklet "What Everyone Should Know About Leukemia," write to: Leukemia Society of America, 733 Third Ave., New York, New York 10017.

leukemia®
society of america, inc.

We're closing in on a killer.

* leukemia and related diseases

To understand much of what we're doing with respect to cancer research, you'd need a graduate degree in microbiology or biochemistry.

But to understand how well our educational programs and service resources help both patients and their families, simply talk to one out of every 100 Americans who are part of our volunteer program. Or talk to one of the 3 million who've survived cancer.

The battle isn't over but we are winning.

Please support the American Cancer Society.

Health Care Opportunities In The Kingdom Of Saudi Arabia

Exceptional opportunities are available at the **King Faisal Specialist Hospital and Research Centre.** The Hospital, located in Riyadh, Saudi Arabia is a 500-bed acute care facility with an international staff.

Positions are currently available for:

HEMATOLOGIST/ ONCOLOGIST
BMT experience desirable

MEDICAL TECHNOLOGISTS
Hematology

To be considered for this opportunity, physicians must be board certified in the specialty area and have current U.S., Canadian or U.K. license to practice. University affiliation and administrative experience is preferred. Requirements for Medical Technologists include BSMT degree, MT (ASCP) certification and 2 years current experience as a Med Tech (at least 6 months in Hematology).

The benefits are outstanding and include modern, high quality furnished housing, airfare, 30 day annual paid vacation, plus 20 additional leave days, bonus pay and leave and more. The selected candidates will be employed by and have a contract with the government of the Kingdom of Saudi Arabia.

If you would like to become a part of this multi-national health care team, please call our toll-free number **(800) 251-2561** (in Tennessee **(800) 342-2110**) or send your resume to: **HCA International Company, Dept. BL-0186, P.O. Box 550, Nashville, TN 37202.** HCA is an Equal Opportunity Employer.

ADVANCES IN HAEMATOLOGY 1986
9–13 June 1986

This is a five-day course for specialists and trainees in haematology, with emphasis on progress in the fundamental basis of blood disorders, their diagnosis and their treatment.

Topics include haemopoietic cell cultures; blood cell genes newly cloned; immune and auto-immune disorders; bone marrow transplant; biology and therapy of acute leukaemias; new diagnostic methods in haematology.

There will be lectures, clinical case presentations, a clinicopathological conference and diagnostic slide sessions. Speakers will be members of the Department of Haematology and the MRC Leukaemia Unit (D. Catovsky, D.A.G. Galton, J.M. Goldman, E.C. Gordon-Smith, J. Hows, S.M. Lewis and L. Luzzatto) as well as eminent guest lecturers.

Course Organisers: Drs. S.M. Lewis and J.M. Goldman.

Course fee (including catering): £200.

Application forms from: School Office (SSC), Royal Postgraduate Medical School, Hammersmith Hospital, Du Cane Road, London W12 OHS, Tel: 01-743 2030 Ext 351.

Academic Hematologist—BC/BE to join combined Oncology/Hematology section at the University of Nebraska Medical Center. The candidate will participate in established programs in bone marrow transplantation and treatment of hematologic/thrombotic disorders and is expected to develop an active research program. Please send inquiries with C.V. to Jonathan C. Goldsmith, M.D., Department of Internal Medicine, University of Nebraska Medical Center, 42nd and Dewey Avenue, Omaha, Nebraska 68105. The University of Nebraska Medical Center is an Affirmative Action/Equal Opportunity employer.

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to BLOOD. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: BLOOD will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the BLOOD Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in BLOOD represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a $50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to:

John W. Adamson, MD, Editor
BLOOD
University District Building—Room 320
1107 NE 45th St
Seattle, WA 98105

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of BLOOD will assume that the authors of research papers published in BLOOD are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and *two* complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least 1/12 inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus.* (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

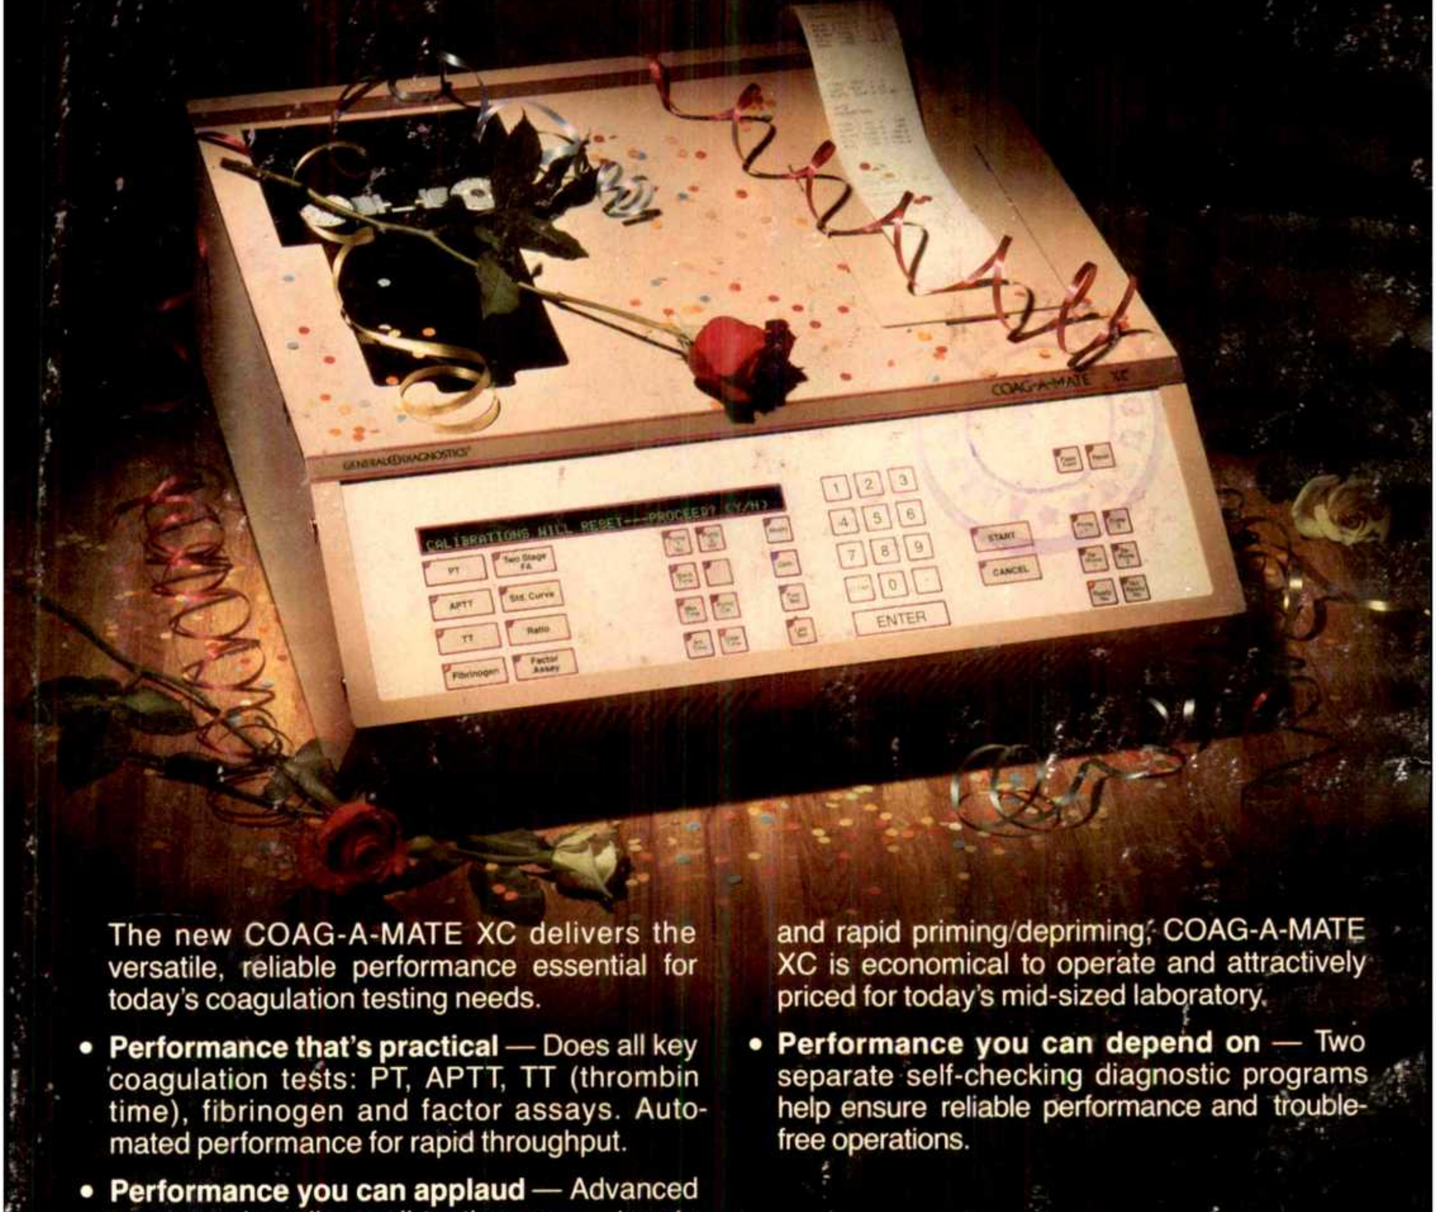
BRAVO!

Introducing the Versatile Performer New COAG-A-MATE® XC



The new COAG-A-MATE XC delivers the versatile, reliable performance essential for today's coagulation testing needs.

- **Performance that's practical** — Does all key coagulation tests: PT, APTT, TT (thrombin time), fibrinogen and factor assays. Automated performance for rapid throughput.
- **Performance you can applaud** — Advanced programming allows all testing parameters to be temporarily or permanently modified by operator, with results expressed in %, ratio, seconds or mg/dl. Holds up to 15 standard curves in permanent memory.
- **Performance you can afford** — Equipped with numerous labor- and time-saving features, like semiautomated pump calibration and rapid priming/depriming, COAG-A-MATE XC is economical to operate and attractively priced for today's mid-sized laboratory.
- **Performance you can depend on** — Two separate self-checking diagnostic programs help ensure reliable performance and trouble-free operations.

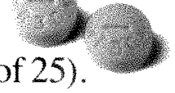
derate Rescue

WELLCOVORIN®
TABLETS
(leucovorin calcium)

The First Leucovorin Rescue With Oral Convenience

As a result of advanced technology,
Wellcovorin is the first leucovorin calcium available in convenient tablet form.
With Wellcovorin Tablets, no reconstitution of vials, mixing of special solutions,
or cumbersome breaking of ampuls is necessary.

For greater flexibility in oral dosing, Wellcovorin Tablets come
in two sizes: 5 mg (scored, bottles of 100) and 25 mg (scored, bottles of 25).



Consider Enhanced Quality of Life:

Often discharged from the hospital earlier, many patients can complete their course of therapy on an outpatient basis and return to a more normal, comfortable lifestyle sooner.

Consider Less Costly Care:

Mg for mg, Wellcovorin Tablets are less expensive than injectable leucovorin. Plus, with Wellcovorin Tablets, hospital stays are often shorter and clinic visits less frequent.

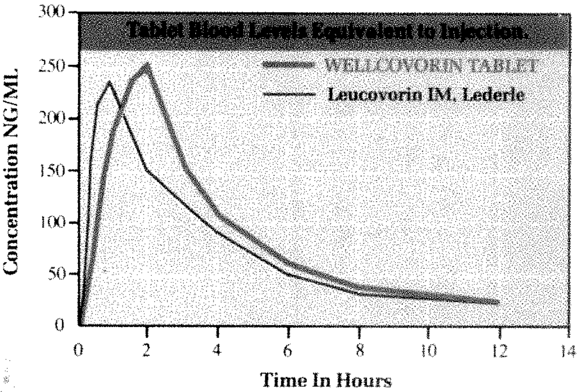
Consider Greater Patient Comfort:

Patients no longer need to drink special liquid formulations or endure a series of painful needle punctures. Patients simply take the prescribed number of Wellcovorin Tablets with water.

Consider Assured Blood Levels:

Wellcovorin Tablets are bioequivalent to equal amounts of injectable leucovorin, whether it is administered intravenously or intramuscularly (peak serum concentrations are reached after approximately two hours).

Blum MR, Guaspari A, Liao SHT, et al. Bioavailability and pharmacokinetics of oral and parenteral leucovorin. 33rd National Meeting Pharm Sci, San Diego, California, 1982, 12(2):175



Average serum folates after single 15 mg dose of leucovorin administered either IM or orally.

WELLCOVORIN® TABLETS
(leucovorin calcium)
Leucovorin in convenient 5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m² orally or parenterally followed by 10 mg/m² orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m² every three hours until the serum methotrexate level is below 5×10^{-8}M.[1,2]

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[3,4,5]

BLOOD

The Journal of The American Society of Hematology

Blood: The Journal of The American Society of Hematology (ISSN 0006–4971) is published monthly, in two volumes per year, at 6277 Sea Harbor Drive in Orlando, FL 32821. Second class postage paid at Orlando, FL, and at additional mailing offices.

Editorial correspondence should be addressed to:
John W. Adamson, MD, Editor
BLOOD
University District Building—Room 320
1107 NE 45th St
Seattle, WA 98105

Correspondence regarding subscriptions or change of address should be addressed to Grune & Stratton, Inc., Journal Subscription Fulfillment Department, 6277 Sea Harbor Drive, Orlando, FL 32821.

Change of address notices, including both the subscriber's old and new address, should be sent to the publisher at least one month in advance.

Other correspondence (copyediting, production) should be addressed to:
Ms Carol Leach, Managing Editor
BLOOD
Grune & Stratton, Inc.
Orlando, FL 32887

Customer Service: (305) 345-2777.

Subscription rates: $113.00 per year within the United States and Canada; elsewhere, $127.00 per year; libraries and institutions, $139.00 per year within the United States and Canada; elsewhere, $147.00 per year. Students, fellows, interns, and residents may receive a reduced subscription rate: $53.00 per year within the United States and Canada; elsewhere, $57.00 per year. A letter giving qualifying data must accompany such orders. Single copies: United States and Canada, $16.00; elsewhere, $17.00. Back issue and back volume prices are those in current effect. Single issues, both current and back, exist in limited quantities and are offered for sale subject to availability. Subscriptions are accepted on a calendar-year basis. Journal orders are payable in advance. Prices are subject to change.

Advertising Representative: Cunningham Associates, PO Box 308, Park Ridge, NJ 07656, telephone (201) 767-4170.

Agents for Great Britain: Grune & Stratton, Ltd, 24–28 Oval Rd, London NW1 7DX, England. Agents for Australia and New Zealand: Grune & Stratton Australia, PO Box 300, North Ryde, NSW 2113, Australia. Publication of an advertisement in *Blood* does not imply endorsement of its claims by The American Society of Hematology or by the Editors or Publisher of the journal.

The appearance of the code at the bottom of the first page of an article in this journal indicates the copyright owner's consent that copies of the article may be made for personal or internal use, or for the personal or internal use of specific clients. This consent is given on the condition, however, that the copier pay the stated per-copy fee through the Copyright Clearance Center, Inc for copying beyond that permitted by Sections 107 or 108 of the US Copyright law. This consent does not extend to other kinds of copying, such as copying for general distribution, for advertising or promotional purposes, for creating new collective works, or for resale. Absence of the code indicates that the material may not be processed through the Copyright Clearance Center.

Postmaster: Send change of address to *Blood,* c/o Grune & Stratton, Inc., Journal Subscription Fulfillment Department, 6277 Sea Harbor Drive, Orlando, FL 32821. Return postage guaranteed.

The American Society of Hematology certifies that the continuing medical education offering provided by BLOOD, The Journal of The American Society of Hematology, meets the criteria for up to 22 hours of credit in Category 5(a) for the Physician's Recognition Award of the American Medical Association.

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

(Contents continued)

Effective January 1, 1986, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $30.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

All manuscripts submitted for consideration for publication in BLOOD should be sent to: John W. Adamson, MD, Editor, BLOOD, University District Building—Room 320, 1107 NE 45th St, Seattle, WA 98105.

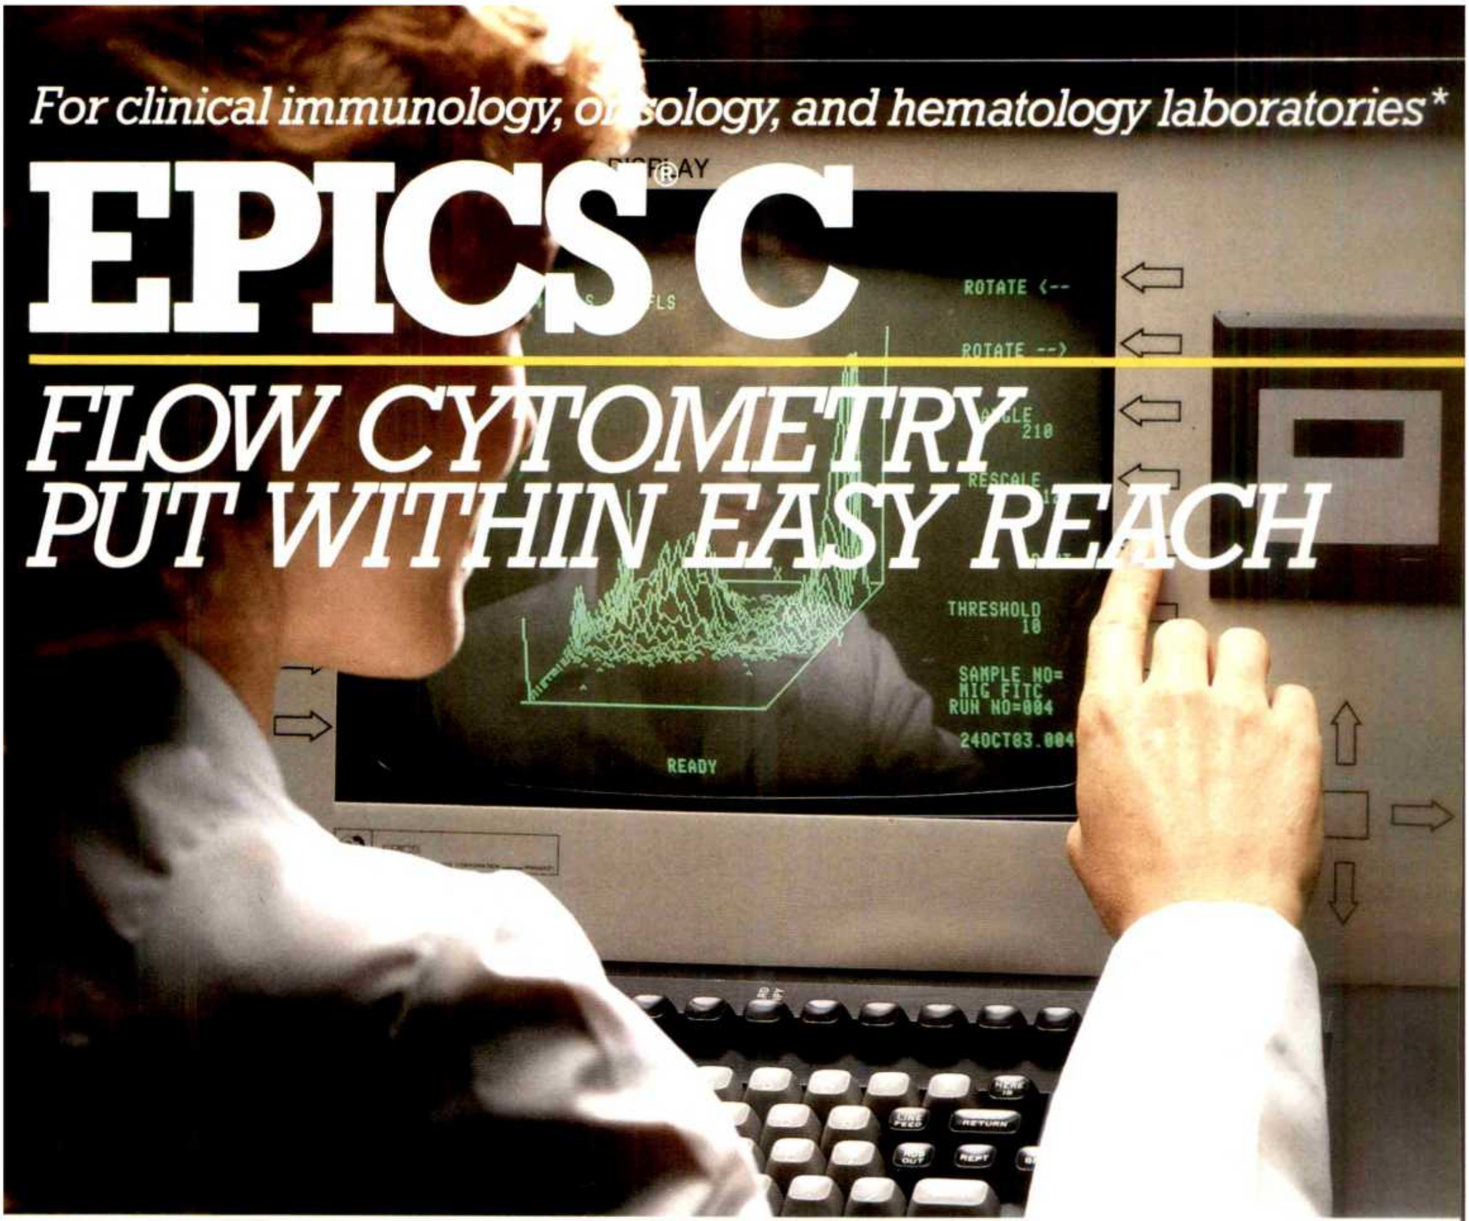
Please note that a processing fee of $50.00 must accompany each manuscript submitted for publication in BLOOD.

The American Society of Hematology certifies that the continuing medical education offering provided by *BLOOD, The Journal of The American Society of Hematology*, meets the criteria for up to 22 hours of credit in Category 5(a) for the Physician's Recognition Award of the American Medical Association.

*For clinical immunology, oncology, and hematology laboratories**

EPICS® C

FLOW CYTOMETRY PUT WITHIN EASY REACH



With ease of input

fast sample preparation of dual-color labeling in whole blood is ready in less than one hour

convenient touchpad operation provides automatic control for your protocol configuration and analysis selection, and eliminates lengthy or complex computer interface

easily aligned straight-through optics remain stable, resulting in precise and reproducible measurements

computerized graphics display different cell types and percents of each population with superior resolution, using three-dimensional histograms and contours

automated analysis and sorting processes up to 10,000 cells per second; sorts more than 5,000 cells per second for fast and accurate results

easy-to-modify protocols give you the flexibility of choosing from preprogrammed protocols or redesigning them to meet special needs

EPICS DIVISION
OF COULTER CORPORATION Hialeah, Fl

Artfully advancing the science of flow cytometry

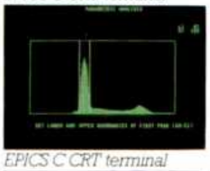
**More than 150 EPICS C systems are in use worldwide to date, with numerous applications*

For depth of insight

The EPICS C flow cytometry system is equipped to provide your clinical lab with new insights into a variety of diseases. The unique *straight-through* optics focus a *high-powered laser* on individual human cells, while a *built-in computer* precisely analyzes the patient sample. Data collected on the EPICS C can be displayed on either the EPICS C or Easy System CRT terminals.

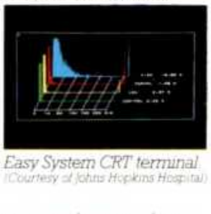
EPICS C CRT terminal

In immunology: Many immunological disorders, including leukemia and AIDS, have telltale leukocyte abnormalities. The EPICS C analyzes white blood cells and displays graphs of their subpopulations (lymphocytes, monocytes, and granulocytes) for additional information on these diseases.



EPICS C CRT terminal

In oncology: Through the use of PARA 1 software on the EPICS C, the relative number of cells in each phase of the cell cycle can be determined. Aneuploid populations, tumor cells that contain an abnormal amount of DNA, can appear as separate peaks on a DNA histogram and can be quantitated.



Easy System CRT terminal
(Courtesy of Johns Hopkins Hospital)

In hematology: The EPICS C provides reliable and automated reticulocyte enumeration. In only two minutes, the EPICS C can automatically count 100,000 total cells, minimizing sampling error of tedious manual procedures.

Aggressive antibody protection against overwhelming infection for the immune-compromised patient
IMMUNE DEFENSE

NOW INDICATED FOR ITP

GAMIMUNE®

Immune Globulin Intravenous 5% (in 10% maltose)

The original IGIV... and still the clinical standard

The only IGIV proven by over three years of successful clinical experience in the United States.
Safe and effective use with more than 200,000 infusions has established GAMIMUNE as the IGIV of choice for patients with impaired humoral immune response who require rapid, broad-spectrum antibody protection.

The only ready-to-infuse, liquid IGIV.
The superior, patented GAMIMUNE formulation offers a significant advantage in IGIV therapy. Unlike lyophilized IGIV products, which can take up to 20 minutes for reconstitution, and which must be used immediately thereafter, GAMIMUNE is premixed, premeasured and can be stored under stated conditions for up to two years without increasing the risk of anticomplementary aggregate formation.

Speed...spectrum...and safety.
Infusion with GAMIMUNE rapidly provides high titers of antibody specific to a wide range of commonly occurring bacterial, viral and fungal pathogens—safely and with little or no patient discomfort. An unmatched, three-year safety record confirms: GAMIMUNE carries virtually no risk of serious anticomplementary side effects.[1,2] And, GAMIMUNE meets or exceeds all WHO standards for IGIV preparation.

Unsurpassed IGIV therapeutic efficacy.
The integrity of IgG molecules in GAMIMUNE is preserved in the reduction and alkylation process; antibodies remain functionally complete, possessing the full biologic activity of native immunoglobulin.[3,4,5]

FROM WITHIN

GAMIMUNE®

Immune Globulin Intravenous, 5% (In 10% maltose)

DESCRIPTION

Immune Globulin Intravenous, 5% in 10% Maltose (IGIV, 5% Maltose) Gamimune® is a sterile 5 ± 1% solution of human protein stabilized with 10 ± 2% maltose; it contains no preservatives. The immunoglobulin is selectively reduced under controlled conditions using dithiothreitol and alkylated with iodoacetamide to render it suitable for intravenous administration. Each 10 mL contains approximately 500 mg of protein, not less than 90% of which is immunoglobulin. Thus, there are approximately 450 mg of immunoglobulin in each 10 mL of IGIV, 5% Maltose. The pH is 5.25 ± 0.25. The calculated osmolality is 327 milliosmoles per kilogram of solvent (water) and the calculated osmolarity is 292 milliosmoles per liter of solution. The product is prepared by cold alcohol fractionation from large pools of human venous plasma. Each individual unit of plasma has been tested and found nonreactive for hepatitis B surface antigen (HBsAg) using a test with third-generation sensitivity.

CLINICAL PHARMACOLOGY

Gamimune supplies IgG antibodies for prevention or attenuation of infectious diseases. The half-life of Gamimune is approximately three weeks but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immunoglobulin administered per dose is important in determining the frequency of administration of the drug for each patient.

While intravenous immunoglobulin has been shown to be effective in some cases of idiopathic thrombocytopenic purpura (ITP) (see Indications and Usage), the mechanism of action in ITP has not been fully elucidated.

Maltose is added to the solution in a 10% concentration for stabilization of the protein. A comparative clinical study of IGIV with and without maltose showed the incidence of adverse effects was significantly less with the maltose-containing preparation.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well and no adverse effects were observed at a rate of 0.25 g maltose/kg per hour. In safety studies conducted by Cutter Laboratories, infusions of 10% maltose administered at 0.27 to 0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous infusions of maltose, maltose was detected in the peripheral blood, and there was a dose dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were tolerated without significant adverse effects.

Since one milliliter of Immune Globulin Intravenous, 5% in 10% Maltose (IGIV, 5% Maltose) Gamimune® contains 0.1 g of maltose, the recommended dose of Gamimune (0.1 g to 0.4 g per kilogram body weight) would result in the patient receiving a total of 0.2 g to 0.8 g maltose per kilogram body weight given over several hours. These amounts are within those levels tolerated in the Cutter safety studies cited above.

INDICATIONS AND USAGE

Immunodeficiency Gamimune is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune may be preferred to that of intramuscular immunoglobulin preparations especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., x-linked agammaglobulinemia), common variable hypogammaglobulinemia, x-linked immunodeficiency with hyper IgM, and combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura Some children and adults with ITP have shown an increase (albeit temporary) in platelet counts upon administration of Gamimune. Therefore administration of Gamimune should be considered in situations that require a rapid, temporary rise in the platelet count, for example, prior to surgery or to control excessive bleeding. However, it should be noted that not all patients will respond. Even in those patients who do respond, this treatment should not be considered to be curative.

CONTRAINDICATIONS

Immune Globulin Intravenous, 5% in 10% Maltose (IGIV, 5% Maltose) Gamimune® is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Serum Globulin (Human). Individuals with selective IgA deficiencies who have known anti-IgA antibody should not receive IGIV, 5% Maltose since these patients may experience severe anaphylactic reactions to even small amounts of immune globulin preparations.

WARNINGS

IGIV, 5% Maltose should be administered only intravenously as the intramuscular route has not yet been evaluated.

> IGIV, 5% Maltose can, on occasion, cause a precipitous fall in blood pressure and the clinical picture of anaphylaxis even when the patient is not known to be sensitive to immune globulin preparations. These reactions appear to be related to the rate of infusion. Accordingly, the infusion rate given under Dosage and Administration should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for treatment of any acute anaphylactoid reaction.

PRECAUTIONS

General Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid.

Drug Interactions If dilution is required Gamimune may be diluted with 5% dextrose. No other drug interactions or compatibilities have been evaluated. It is recommended that the infusion of Gamimune be given via separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C Animal reproduction studies have not been conducted with Immune Globulin Intravenous, 5% in 10% Maltose (IGIV, 5% Maltose) Gamimune®. It is also not known whether Gamimune can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune should be given to a pregnant woman only if clearly needed.

Pediatric Use High dose administration of Gamimune in children with idiopathic thrombocytopenic purpura (ITP) did not reveal any adverse effects specific to the pediatric age group.

ADVERSE REACTIONS

In a small safety study of Gamimune in ten patients with primary immunodeficiency diseases, who received a total of 28 infusions at a dose of 400 mL per kg body weight, there were no adverse reactions reported during any of the infusions. Post infusion, three patients reported adverse effects "possibly" or "definitely" related to the IGIV infusion; two patients experienced post-infusion headache, and one had a flu like syndrome consisting of joint pain, red eyes, and fatigue following the infusion.

During additional investigational studies, 17 other patients with idiopathic thrombocytopenic purpura (ITP) received a total of 148 infusions of Gamimune. Most of these infusions were at doses of 400 mg/kg body weight for 5 consecutive days; however, some patients received either 400 mg/kg or 800 mg/kg body weight as a single infusion intermittently. In these studies, adverse reactions were reported in 17 of 148 (11.5%) infusions of Gamimune. Headache, generally mild, was the most common symptom noted, occurring during or following 8% of infusions. Other less frequently reported symptoms included emesis, chills, fever, chest tightness, and nausea. With rare exceptions, symptoms were either mild or moderate in degree.

Potential reactions with administration of intravenous gamma globulins may also include anxiety, flushing, chills, wheezing, abdominal cramps, back pain, myalgia, arthralgia, malaise and dizziness; rash has been reported only rarely. These reactions tend to be related to the rate of infusion; their management is described under Dosage and Administration.

True anaphylactic reactions to IGIV, 5% Maltose may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immune serum globulin, but some patients may tolerate cautiously administered IGIV without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immune globulin.

DOSAGE AND ADMINISTRATION

Prophylaxis of Immunodeficiency Syndromes: The usual dose of Gamimune for prophylaxis in immunodeficiency syndromes is 100 mg/kg body weight (i.e., 2 mL/kg body weight) administered once a month by intravenous infusion. If the clinical response is inadequate or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be increased to 200 mg/kg body weight (i.e., 4 mL/kg body weight) or the infusion may be repeated more frequently than once a month.

Therapy of Idiopathic Thrombocytopenic Purpura (ITP): The recommended dosage of Gamimune for therapy of ITP is 400 mg/kg of body weight (i.e., 8 mL/kg body weight) on five consecutive days.

Administration: Recent investigations confirm that Gamimune is well tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune be infused, by itself, at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes. If the patient does not experience any discomfort, the rate may be gradually increased to between 0.02 and 0.04 mL/kg body weight per minute. If side effects occur, the rate should be reduced or the infusion interrupted until the symptoms subside. The infusion may then be resumed at a rate which is tolerated by the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Twenty years ago, leukemia* killed enough people to fill the Houston Astrodome.

Twenty years ago, leukemia was a mysterious disease. Little was known about the cause. Less was known about the cure.

But since then, the Leukemia Society of America has funded 32 million dollars of medical research in an all-out effort to find a cure.

Today, more and more people with leukemia are surviving. Living normal lives. But the Leukemia Society won't be satisfied till this killer is stopped for good.

For more information, including the free booklet "What Everyone Should Know About Leukemia," write to: Leukemia Society of America, 733 Third Ave., New York, New York 10017.

The newest volume in an authoritative series!

PROGRESS IN LIVER DISEASES, VOLUME VIII

Edited by

Hans Popper, M.D., Ph.D. **Fenton Schaffner, M.D., M.S.**

Progress in Liver Diseases, Volume VIII continues in the tradition of providing authoritative reviews of published data on the liver and its diseases.

This volume includes up-to-date coverage of cell pathobiology and molecular biology. Common hepatic diseases, forms of cholestasis, and alcoholic liver injury are also discussed. Types of viral hepatitis, including delta agent disease, are covered in a major section, along with the hepatitis B vaccine and the relation of hepatitis B infection to hepatocellular carcinoma. This comprehensive survey of the current status of liver diseases will benefit specialists and residents in hepatology, gastroenterology, and internal medicine.

TENTATIVE CONTENTS (Partial): *Kamal G. Ishak,* Applications of Scanning Electron Microscopy to the Study of Liver Disease. *Christiane Guguen-Guillouzo, Michel Bourel, and André Guillouzo,* Human Hepatocyte Cultures. *Jeffrey M. Hoeg and H. Bryan Brewer, Jr.,* Human Lipoprotein Metabolism and the Liver. *David Zakim,* The Role of Membrane Lipids in the Regulation of Membrane-Bound Enzymes. *Luigi M. DeLuca and Kim E. Aggressive Therapy for

Aggressive Lymphomas

Approaching a cure for non-Hodgkin's lymphomas (NHL)

Lymphomas were considered incurable a scant two decades ago; now, cure is a reality for as many as half of all patients with NHL.[1] The frequency of complete remissions—the most critical factor influencing prognosis—has increased, and long-term disease-free survival is an attainable goal for many patients.

With innovative therapeutic programs

Combination chemotherapy now serves as a primary therapy for the vast majority of patients with intermediate-to-poor prognosis NHL. Treatment strategies depend on many factors, including age, histology, and stage of the primary disease, and presence of comorbid disease. Consequently, no one therapeutic program can be cited as best. Fortunately, the availability of multiple non-cross-resistant regimens has permitted individualization of therapy.

Methotrexate...a component of aggressive regimens improving the outcome in NHL

Lederle introduced Methotrexate in the 1950s. Since then, Methotrexate has been used in many different ways, reflecting the changing approaches to clinical oncology. One important application is in the treatment of NHL.

1. DeVita VT Jr, Hellman S: Hodgkin's disease and the non-Hodgkin's lymphomas, in DeVita VT Jr, Hellman S, and Rosenberg SA (eds): *Cancer: Principles and Practice of Oncology.* Philadelphia, J.B. Lippincott Company, 1982, p. 1392.

Please review the brief summary of prescribing information on the next page

LEDERLE
METHOTREXATE

METHOTREXATE
Brief Summary

WARNINGS:

WARNING
METHOTREXATE MUST BE USED ONLY BY PHYSICIANS EXPERIENCED IN ANTIMETABOLITE CHEMOTHERAPY. BECAUSE OF THE POSSIBILITY OF FATAL OR SEVERE TOXIC REACTIONS, THE PATIENT SHOULD BE FULLY INFORMED BY THE PHYSICIAN OF THE RISKS INVOLVED AND SHOULD BE UNDER HIS CONSTANT SUPERVISION. DEATHS HAVE BEEN REPORTED WITH THE USE OF METHOTREXATE IN THE TREATMENT OF PSORIASIS.

IN THE TREATMENT OF PSORIASIS, METHOTREXATE SHOULD BE RESTRICTED TO SEVERE RECALCITRANT, DISABLING, PSORIASIS WHICH IS NOT ADEQUATELY RESPONSIVE TO OTHER FORMS OF THERAPY, BUT ONLY WHEN THE DIAGNOSIS HAS BEEN ESTABLISHED, AS BY BIOPSY AND/OR AFTER DERMATOLOGIC CONSULTATION.

1. Methotrexate may produce marked depression of bone marrow, anemia, leukopenia, thrombocytopenia, and bleeding.
2. Methotrexate may be hepatotoxic, particularly at high dosage or with prolonged therapy. Liver atrophy, necrosis, cirrhosis, fatty changes, and periportal fibrosis have been reported. Since changes may occur without previous signs of gastrointestinal or hematologic toxicity, it is imperative that hepatic function be determined prior to initiation of treatment and monitored regularly throughout therapy. Special caution is indicated in the presence of preexisting liver damage or impaired hepatic function. Concomitant use of other drugs with hepatotoxic potential (including alcohol) should be avoided.
3. Methotrexate has caused fetal death and/or congenital anomalies; therefore, it is not recommended in women of childbearing potential unless there is appropriate medical evidence that the benefits can be expected to outweigh the considered risks. Pregnant psoriatic patients should not receive Methotrexate.
4. Impaired renal function is usually a contraindication.
5. Diarrhea and ulcerative stomatitis are frequent toxic effects and require interruption of therapy; otherwise hemorrhagic enteritis and death from intestinal perforation may occur.

METHOTREXATE HAS BEEN ADMINISTERED IN VERY HIGH DOSAGE FOLLOWED BY LEUCOVORIN RESCUE IN EXPERIMENTAL TREATMENT OF CERTAIN NEOPLASTIC DISEASES. THIS PROCEDURE IS INVESTIGATIONAL AND HAZARDOUS.

INDICATIONS: Antineoplastic Chemotherapy: Methotrexate is indicated for treatment of gestational choriocarcinoma, in patients with chorioadenoma destruens and hydatidiform mole; palliation of acute lymphocytic leukemia, treatment and prophylaxis of meningeal leukemia, and palliation of acute lymphoblastic (stem-cell) leukemias in children. May be used for induction of remission in combination with other anticancer drugs or suitable agents, but is most commonly used in maintenance of induced remissions. May be used alone or in combination with other anticancer agents in management of breast cancer, epidermoid cancers of the head and neck, and lung cancer, particularly squamous cell and small cell types. Also effective in treatment of advanced stages of lymphosarcoma, particularly in children, and in advanced cases of mycosis fungoides. See box warnings re *Psoriasis Chemotherapy*, because of high risk Methotrexate is indicated only in symptomatic control of severe, recalcitrant, disabling psoriasis which is not adequately responsive to other forms of therapy, *only when diagnosis has been established, as by biopsy and/or after dermatologic consultation.*
CONTRAINDICATIONS: Psoriatic patients who are pregnant, or have severe renal or hepatic disorders; or have preexisting blood dyscrasias such as bone marrow hypoplasia, leukopenia, thrombocytopenia, or anemia, should not receive Methotrexate.
PRECAUTIONS: Methotrexate has high potential toxicity, usually dose-related; physicians should be familiar with various characteristics and its established clinical usage. Subject patients to appropriate supervision to detect and evaluate signs or symptoms of possible toxic effects or adverse reactions with minimal delay. Hematopoietic suppression is a common effect of Methotrexate; pretreatment and periodic hematologic studies are essential to its use in chemotherapy. This effect may occur abruptly and on apparently safe dosage; any profound drop in blood-cell count indicates immediate stopping of drug and appropriate therapy. Use drug with caution, if at all, in patients with malignant disease who have preexisting bone marrow aplasia, leukopenia, thrombocytopenia, or anemia.

Methotrexate is excreted principally by the kidneys; use in the presence of impaired renal function may result in accumulation of toxic amounts or additional renal damage. Renal status should be determined prior to and during therapy; exercise proper caution should significant renal impairment be disclosed. Reduce or discontinue drug dosage until renal function is improved or restored.

The following laboratory tests are recommended as part of essential clinical evaluation and appropriate monitoring of patients to determine any existing organ dysfunction or system impairment: complete hemogram, hematocrit, urinalysis, renal function and liver function tests, and chest x-ray. Perform tests prior to, at appropriate periods during, and after termination of therapy. Where high dose or long-term therapy is followed, performance of liver biopsy or bone marrow aspiration studies may be useful or important. Methotrexate is bound in part to serum albumin after absorption; toxicity may be increased because of displacement by drugs such as salicylates, sulfonamides, diphenylhydantoin, phenylbutazone; by antibacterials such as tetracycline, chloramphenicol and para-amino-benzoic acid. Do not give these drugs concurrently, especially salicylates, phenylbutazone, and sulfonamides, whether antibacterial, hypoglycemic or diuretic, until significance of these findings is established. Vitamin preparations containing folic acid or its derivatives may alter responses to Methotrexate. Use with extreme caution in presence of infection, peptic ulcer, ulcerative colitis, debility, and extreme youth or old age. Bacterial infection may occur or become a threat if profound leukopenia occurs during therapy; cessation of drug and appropriate antibiotic therapy is usually indicated. Blood or platelet transfusions may be necessary in severe bone marrow depression. Methotrexate may have an immunosuppressive action; take into consideration when immune responses in a patient may be important or essential. In all instances, physician must evaluate need and usefulness of drug against risk of toxic effects or adverse reaction; most adverse reactions are reversible if detected early. Reduce dosage or discontinue drug when such effects or reactions do occur; take appropriate corrective measures according to clinical judgement of physician. Reinstitute therapy with caution, consideration of further need for drug, and alertness to possible toxicity recurrence.
ADVERSE REACTIONS: Most common include ulcerative stomatitis, leukopenia, nausea and abdominal distress. Others reported are malaise, undue fatigue, chills and fever, dizziness and decreased resistance to infection. Incidence and severity of side effects are generally considered dose-related. *Skin*: erythematous rashes, pruritus, urticaria, photosensitivity, depigmentation, alopecia, ecchymosis, telangiectasia, acne, furunculosis. Concomitant exposure to ultraviolet radiation may aggravate lesions of psoriasis. *Blood*: bone marrow depression, leukopenia, thrombocytopenia, anemia, hypogammaglobulinemia, hemorrhage from various sites, septicemia. *Alimentary System*: gingivitis, pharyngitis, stomatitis, anorexia, vomiting, diarrhea, hematemesis, melena, gastrointestinal ulceration and bleeding, enteritis, hepatic toxicity resulting in acute liver atrophy, necrosis, fatty metamorphosis, periportal fibrosis, or hepatic cirrhosis. *Urogenital System*: renal failure, azotemia, cystitis, hematuria, defective oogenesis or spermatogenesis, transient oligospermia, menstrual dysfunction, infertility, abortion, fetal defects, severe nephropathy. *Pulmonary System*: Interstitial Pneumonitis. Deaths have been reported; chronic interstitial obstructure pulmonary disease has occasionally occurred. *CNS*: headaches, drowsiness, blurred vision. Aphasia, hemiparesis, paresis and convulsions have also occurred. Leucoencephalopathy following intravenous administration to patients who have had craniospinal irradiation has been reported. CNS toxicity which may occur after intrathecal use can be classified as follows: 1) chemical arachnoiditis manifested by such symptoms as headache, back pain, nuchal rigidity, and fever; 2)paresis, usually transient, manifested by paraplegia associated with involvement with one or more spinal nerve roots; 3) leucoencephalopathy manifested by confusion, irritability, somnolence, ataxia, dementia, and occasionally major convulsions.

Other reactions related or attributed to Methotrexate, such as metabolic changes, precipitating diabetes, osteoporotic effects, abnormal tissue cell changes and even sudden death have been reported.

ANTIDOTE FOR OVERDOSAGE Leucovorin (citrovorum factor) is a potent agent for neutralizing immediate toxic effects of Methotrexate on the hematopoietic system. Where large doses or overdoses are given, Calcium Leucovorin may be administered by intravenous infusion in doses up to 75 mg within 12 hours, followed by 12 mg intramuscularly every 6 hours for 4 doses. Where average doses of Methotrexate appear to have an adverse effect, 2 to 4 ml (6 to 12 mg) of Calcium Leucovorin may be given intramuscularly every 6 hours for 4 doses. In general, where overdosage is suspected, the dose of Leucovorin should be equal to or higher than the offending dose of Methotrexate and should best be administered within the first hour. Use of Calcium Leucovorin after an hour delay is much less effective.
CAUTION: Pharmacist: Because of its potential to cause severe toxicity, Methotrexate therapy requires close supervision of the patient by the physician. Pharmacists should dispense no more than a seven (7) day supply of the drug at one time. Refill of such prescriptions should be by direct order (written or oral) of the physician only.

Ask one of the 3 million Americans who've survived cancer, if the money spent on research is worth it.

We are winning.

Please support the

AMERICAN CANCER SOCIETY®

This space contributed as a public service.

Twenty years ago, leukemia* killed enough people to fill the Houston Astrodome.

Twenty years ago, leukemia was a mysterious disease. Little was known about the cause. Less was known about the cure.

But since then, the Leukemia Society of America has funded 32 million dollars of medical research in an all-out effort to find a cure.

Today, more and more people with leukemia are surviving. Living normal lives. But the Leukemia Society won't be satisfied till this killer is stopped for good.

For more information, including the free booklet "What Everyone Should Know About Leukemia," write to: Leukemia Society of America, 733 Third Ave., New York, New York 10017.

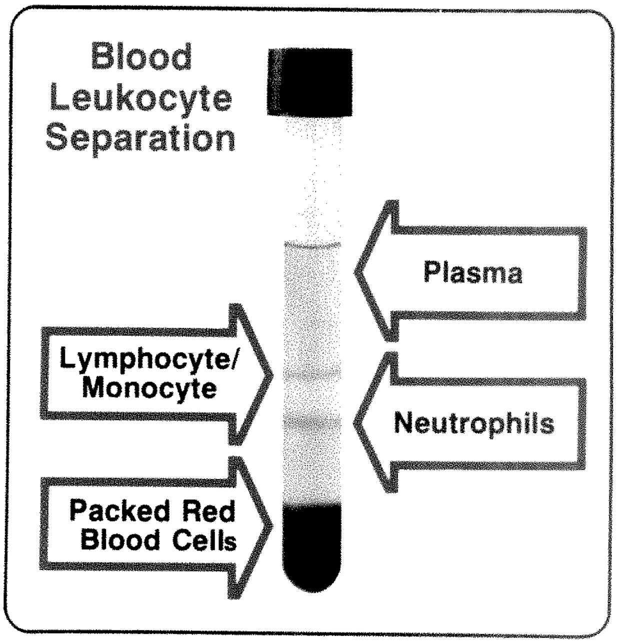
RAPID ONE-STEP
BLOOD LEUKOCYTE SEPARATION



Packard NIM™ (neutrophil isolation medium) reagent provides a quick and easy blood cell separation method. NIM reagent provides:

- 30 minute separation
- A ready to use medium
- Unequaled separation of neutrophils from lymphocytes
- A greater blood capacity for isolation
- A simple procedure
- Undiluted plasma

NIM reagent can also be used to obtain isolated cells for chemiluminescent immunological tests on a PICOLITE® luminometer.

Find out how NIM reagent can work for you. Trial samples are available. Contact Packard for more information on NIM reagent, PICOLITE luminometers, and other chemiluminescent testing reagents.

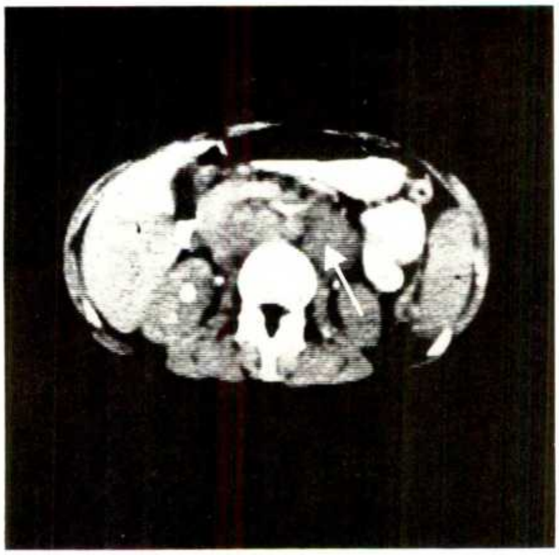
Blenoxane® *Combinations*

(sterile bleomycin sulfate)

Proven Effective in Non-Hodgkin's Lymphoma

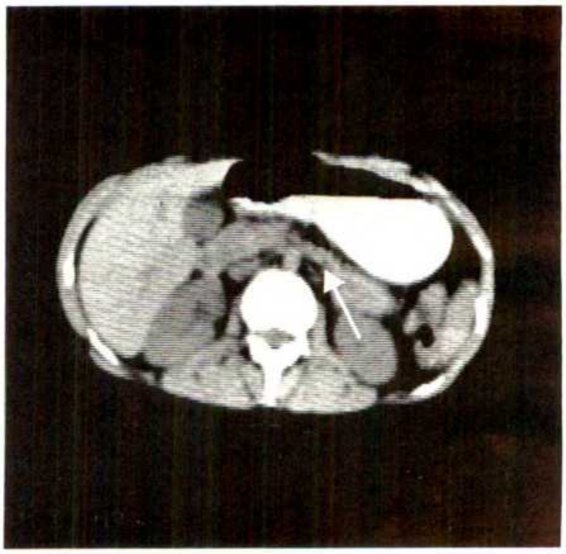
The newer Blenoxane containing combinations resulted in high complete response rates and extended disease-free survival.[1-7]

Abdominal/Pelvic CT
February 25



Massive retroperitoneal, retrocrural, para-aortic, and probable right iliac adenopathy.

Abdominal/Pelvic CT
August 4



No evidence of abnormal abdominal or pelvic adenopathy after Blenoxane combination chemotherapy.

Blenoxane® (sterile bleomycin sulfate) ...Integral Component of Chemotherapy Regimens in Non-Hodgkin's Lymphoma

Since Blenoxane is virtually non-myelosuppressive, continuing therapy with certain Blenoxane containing chemotherapy regimens (e.g. BACOP) can prevent tumor regrowth between cycles of other chemotherapy regimens while allowing for bone marrow recovery.[*2,3,4,6]

Blenoxane can produce, with cumulative doses, a syndrome of pulmonary fibrosis. It is usually dose-related, being seen infrequently in patients whose total dose of Blenoxane is less than 400 units.

Efficacy... Yesterday, Today, Tomorrow

Blenoxane* *(sterile bleomycin sulfate)*

Brief Summary of Prescribing Information (1) 10 84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane* be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma – Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas – Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma – Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary – This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{co}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{co} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{co} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

(1) Maintain $FI\,O_2$ at concentrations approximately that of room air (25%) during surgery and the postoperative period.

(2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions – In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes – These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other – Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban*. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20

ROXANOL 100™ Concentrated Oral Solution Ⓒ

(Morphine Sulfate, Immediate Release)

100 mg per 5 ml (Warning: May be habit forming.)

The most versatile oral morphine

Easy to dose—
from 20 mg to 100 mg.

Easy to administer—
either alone or mixed with a liquid or semisolid food.

Easy to measure—
with a calibrated Patient Spoon™ accompanying every 240 ml bottle.

Easy to account for—
the label of each 240 ml amber glass bottle of Roxanol 100 is clearly calibrated to eliminate guesswork.

**Alcohol-free.
Sugar-free.**

NATIONAL FLOW CYTOMETRY METHODS COURSE

DATES: May 12–16, 1986

LOCATION: Smith Kline & French Laboratories
Philadelphia, PA (USA)

Co-sponsored by

SMITH KLINE & FRENCH LABORATORIES
and
LOS ALAMOS NATIONAL LABORATORY

Co-Directors: Paul Karl Horan, Ph.D. (Smith Kline & French)
L. Scott Cram, Ph.D. (Los Alamos National Laboratory)

A methods course in flow cytometry will be offered with special emphasis on immunology and cell biology. Lectures will include instrumentation description, cytochemistry, immunofluorescence analysis, cell kinetic analysis, and immunobiology. Laboratory sessions will address sample preparation, data collection, and data analysis. Problem solving sessions utilizing flow cytometers will provide ample discussion of typical problems encountered in flow cytometry and how individual faculty members solve these problems. Manual including lecture notes, laboratory procedures, and selected references will be provided.

FACULTY	SUBJECTS
Noel Warner, Ph.D.	Applications in immunobiology
Alan Waggoner, Ph.D.	Fluorescence cytochemistry and probes of cell function
Alemseged Truneh, Ph.D.	Liposomes as fluorescent probes
Dan Pinkel, Ph.D.	*In situ* hybridization for genetic analysis
Katharine Muirhead, Ph.D.	Standards, controls, and calibration
Zdenka Jonak, Ph.D.	Gene analysis methods
James Jett, Ph.D.	Single parameter data analysis
Bruce Jensen, Ph.D.	Cytochemistry and cellular energetics
Paul Karl Horan, Ph.D.	Single and multiple color immunofluorescence methods
Frank Dolbeare, Ph.D.	Anti-BrdU methods for cell kinetic analysis
Zbigniew Darzynkiewicz, Ph.D.	Acridine orange techniques for cell kinetic analysis
L. Scott Cram, Ph.D.	Chromosome analysis
Kenneth D. Bauer, Ph.D.	DNA/oncoprotein analysis of paraffin embedded nuclei
C. Bruce Bagwell, M.D., Ph.D.	Multiparameter data analysis and management

SMITH KLINE & FRENCH SPECIAL LECTURER
DR. JOE GRAY: "The future of single cell genetic analysis"

COST: $525 includes coffee breaks, lunches, laboratory fees, and course manual. Please make checks payable to "Flow Applications Course - FCMA."

ENROLLMENT: To reserve a place (49 persons, maximum), send tuition and CV or statement of flow cytometry experience/interests to

HERPES SIMPLEX INFECTION IN THE COMPROMISED HOST:

OFTEN SERIOUS, TOO OFTEN UNSUSPECTED

Number one in a series of typical case presentations.

Esophagitis in a leukemia patient

In patients with hematologic malignancies, the visceral organ most frequently involved by herpes simplex virus (HSV) infection is the esophagus.[1] Extensive ulcerative lesions may develop on the upper two thirds of the esophagus with confluent lesions of the distal third.[2] In some cases, however, the mucosa may be grossly unremarkable even when microscopic examination shows evidence of herpetic ulcerative esophagitis.[1] Similarly, some patients may display symptoms of dysphagia and burning retrosternal pain,[3] whereas others may appear asymptomatic.[1] The diagnostic method of choice for patients with suspected herpetic esophagitis is esophagoscopy with visualization of the mucosa and procurement of cytologic and biopsy specimens from ulcerated areas.[1]

Herpetic infections may result in extensive disease and death

Immunocompromised patients are highly vulnerable to HSV infection. Such infections may interrupt therapy and even lead to death if not detected early and managed aggressively.[1] Although the initial appearance may be mild, HSV infection may progress to severe localized mucocutaneous ulcerations. The greatest threat that herpes simplex poses is an infection that disseminates from a mucocutaneous or unrecognized primary lesion and involves the lungs, liver, esophagus, or central nervous system.[1] Furthermore, herpetic ulcers frequently provide an entry for secondary bacterial and fungal pathogens.[2]

Infections may not be diagnosed correctly without virologic study

Some investigators claim that the actual incidence of serious HSV infection is probably higher than reported because "the possibility of herpetic disease is insufficiently considered and appropriate diagnostic viral studies are often not carried out."[3] One study, for example, found histocytologic evidence of visceral herpes infection in 56 patients even though herpetic involvement was not suspected in any of the patients prior to autopsy.[2]

ZOVIRAX I.V. halts viral replication and speeds healing even in debilitated patients

ZOVIRAX I.V. has been shown to be a highly effective treatment for severe mucocutaneous HSV infection in immunocompromised patients. In controlled trials, ZOVIRAX I.V. rapidly halted viral shedding — within 3 days in most patients — and significantly shortened healing time as well as duration of pain.[4,5] Furthermore, ZOVIRAX I.V. may allow patients to return home sooner and enable patients with intraoral lesions to resume normal eating habits.[6]

ZOVIRAX I.V. is well tolerated by immunocompromised patients

A multicenter collaborative trial of ZOVIRAX I.V. in immunocompromised patients reported that: "Clinical benefits were obtained without appreciable toxicity. The most common reactions were irritation of peripheral veins used for drug infusion and a low incidence of rash.... Significant renal or hematologic toxicity did not occur, even in these seriously ill patients who were commonly receiving other drugs concomitantly."[5]

Note: Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes. Please see brief summary for more information.

An effective response to a life-threatening infection

ZOVIRAX® I.V. INFUSION

(acyclovir sodium) sterile powder

An effective response to a life-threatening infection

ZOVIRAX® I.V. INFUSION (acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M^2 every 8 hours (750 mg/M^2/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.[1,2,3]

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.[4]

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.[5]

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[6]

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously, or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS and DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M^2) over an hour was associated with a lower frequency — 4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 6 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the I.V. fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonitis, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.8 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitters, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION — RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: ***MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 and HSV-2) INFECTIONS IN IMMUNOCOMPROMISED PATIENTS*** — 5 mg/kg infused at a constant rate over 1 hour, every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M^2 at a constant rate over 1 hour, every 8 hours (750 mg/M^2/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS — The same dose given above — administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M^2)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

SEMINARS IN HEMATOLOGY

Editors

Peter A. Miescher, M.D., and
Ernst R. Jaffé, M.D.

Volume 23, 1986
Published quarterly, approx. 310 pages per year
Annual subscription rate, U.S.A. and Canada:
$52.00 individuals/$68.00 institutions
(All other countries: $75.00)
ISSN: 0037-1963

A topical journal on subjects of current importance in clinical hematology and related fields, **Seminars in Hematology** is devoted to making the present status of such topics and the results of new investigations readily available to the practicing physician. It is of special interest to hematologists, oncologists, internal medicine specialists, blood bankers, and specialists in thrombosis and hemostasis.

SCHEDULED TOPICS, VOLUME 23, 1986:

JANUARY — PLATELETS AND MEGAKARYOCYTES IV
Guest Editors: *Paul K. Schick, M.D., and Helge Stormorken, M.D.*

APRIL — PLATELETS AND MEGAKARYOCYTES V
Guest Editors: *Paul K. Schick, M.D., and Helge Stormorken, M.D.*
POLYCYTHEMIA VERA: AN UPDATE
Guest Editor: *Nathaniel I. Berlin, M.D.*

JULY — LEUKEMIA I
Guest Editor: *Robert Peter Gale, M.D., Ph.D.*

OCTOBER — LEUKEMIA II
Guest Editor: *Robert Peter Gale, M.D., Ph.D.*

TECHNICON H·1 SYSTEM THE INFLUENCE GROWS

It's no wonder that TECHNICON'S sphere of influence in hematology is growing rapidly. All it took was the new TECHNICON H•1™ system. This hematology analyzer is already providing a growing list of labs with a CBC, platelets, a FULL white cell differential, and RBC morphology plus lymphocyte subset analysis. All from one sample, at one work station, in one minute and on one comprehensive report form. As the TECHNICON H•1 systems are delivered, the influence grows. Let us influence you. For more information write: Ms. Lou Ann Page, TECHNICON INSTRUMENTS CORP., 511 Benedict Ave., Tarrytown, NY 10591.

BRIEF REVIEW

Structure, Function, and Molecular Defects of Factor IX

By Arthur R. Thompson

ACROSS 13 generations and 55 affected members, the "bleeders of Tenna" in eastern Switzerland have demonstrated that hemophilia B is not necessarily severe or associated with spontaneous bleeding episodes.[1] Moreover, patients with congenitally deficient factor IX activity are clinically indistinguishable from those with factor VIII deficiency, that is, hemophilia A. Both types of hemophilia are X-linked, and defects leading to the milder forms of either type are actually more prevalent than are clinically severe disorders.* Hemophilia B, formerly known as plasma thromboplastin component (PTC) deficiency, or Christmas disease, occurs in 1 out of every 25,000 males, accounting for nearly one fourth of all patients with hemophilia. A variety of genetic defects would be expected to explain the differences in clinical severity and clotting factor activities found in different families. Considerably more genetic heterogeneity is indicated by the variability of factor IX antigen levels among families with similar clotting factor activities.[2] Although antigen levels are often low in patients with severe hemophilia B, most patients have factor IX antigen detectable by sensitive assays using either polyclonal[2] or monoclonal antibody preparations.[3]

Factor IX is a single chain glycoprotein, representing about one ten thousandth of the total circulating protein in plasma.[4] As with other vitamin K-dependent proteins, after polypeptide synthesis there is an enzymatic modification of glutamyl residues in factor IX's amino terminal portion to form specific calcium-binding sites. In vitro, factor IX is activated by factor XIa, the "contact activation product" of the partial thromboplastin time test. Factor IX activation is the first calcium-dependent reaction in intrinsic system clotting. Unlike other steps in clotting, no protein cofactor has been identified. Furthermore, phospholipids are not required for this reaction. Factor IX can also be activated by the extrinsic system activator, factor VIIa, with its cofactor, tissue thromboplastin or tissue factor.[5] The roles of these or other activating mechanisms as related to normal blood coagulation or pathologic disorders remain to be clarified. Factor IX and, particularly, factor IXa bind specifically to the surface of endothelial cells. It remains to be established if this is the site of activation in vivo. The vascular surface may provide the site where a sufficient localized concentration is achieved to promote intrinsic factor X activation by factor IXa.[6] Phospholipid surface, such as platelet factor 3 in vivo, calcium, and a modified form of factor VIII are established cofactors in the activation of factor X by factor IXa.

Recent developments in the molecular biology of factor IX have yielded information about its genomic structure[7,8] and defined its amino acid sequence as dictated by the nucleotide coding sequence. Extensive comparisons of both genomic and protein structures can now be made with homologous regions of other proteins. Although there is as yet little evidence suggesting how the tertiary structure of the amino-terminal half of factor IX is arranged, immunochemical and binding studies should provide evidence. In contrast, the three-dimensional structure of the active site and contiguous sequences in the heavy chain of bovine factor IXa have been predicted by a computer model.[9] However, additional data are required to elucidate which portions of the factor IXa heavy chain provide substrate specificity, allow for specific cofactor binding, and interact with the amino-terminal domains of the molecule.

GENE STRUCTURE

The factor IX gene is quite large, containing nearly 34 kilobases (kb).[7,8] Only 4% of the nucleotide sequence codes for protein; this is done by eight separate exons. The gene is located near the tip of the long arm of the X chromosome,[10-12] near the fragile site defect, which is associated with a mental retardation syndrome.[13] Of homologous vitamin K-dependent proteins, there are genomic data available on prothrombin[14] and on the cDNAs for factor X[15] and protein C.[16]

---

*There are currently 92 identified patients with hemophilia B from 58 families living in Washington state, a population of 4.2 million. Of these, 20% are severe (that is, having less than 1 U/dL factor IX clotting activity and the occurrence of "spontaneous" bleeding episodes), 48% are moderate (with clotting activities from 1 to 5 U/dL), and 32% are mild (with clotting activities from 6 to 26 U/dL). Note that 100 U/dL corresponds to 100% of a normal plasma pool and that the normal concentration of factor IX in plasma is about 5 $\mu g/mL$.[2]

The genomic structure of factor IX and its relation to the gene product are represented in Fig 1. The first exon consists of a leader sequence and the signal for initiation. Translation probably begins with the codon for a Met residue which is 46 positions before the codon for the amino terminus of the mature protein.[8] The pre-pro sequence codes for a hydrophobic portion and two cysteine residues are contributed by the first exon. This is followed by hydrophilic portion coded for by part of the second exon and terminates in Lys-Arg (the last two residues before the amino-terminal Tyr of the circulating protein). The Arg-Tyr bond is then cleaved by a processing protease[8] to form the species recognized in plasma. The first and second exons are separated by an intron of about 6 kb, whereas the second and third exons have only a short intervening sequence. The balance of the second and third exons code for the Gla domain of factor IX, which contains its gamma-carboxyglutamic acid (Gla) residues. These contribute calcium-binding sites. Exons four and five are separated by a large intron, and each codes for a region in the protein that is homologous with epidermal growth factor.[17] The sixth exon is about 21 kb from the 5' end. It codes for the two activation cleavage sites with flanking sequences.

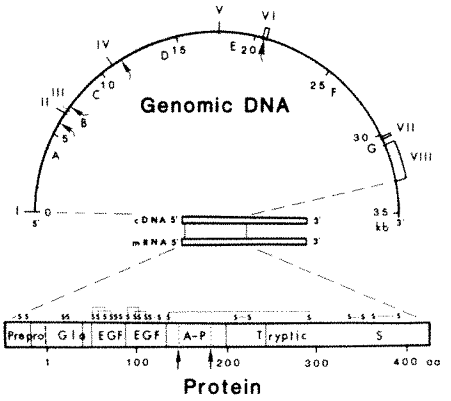

Fig 1. The genomic structure[7,8] of human factor IX is represented in the upper portion by a semicircle from the 5' (left) to the 3' (right) end. Arabic numerals refer to kilobases. Exons, numbered I through VIII, are shown on the outer sides of the semicircle, and introns, lettered from A through G, are on the inner sides of the semicircle. Positions of the four known polymorphisms are indicated by the curved arrows, including a 50-base pair insertion element polymorphic for Hinf I and Dde I near the 3' end of intron A[8,60]; a site polymorphic to Xmn I near the 5' end of intron C[60]; the Taq I polymorphism near the 5' end of intron D[8,11,56]; and the Ala-Thr polymorphism within exon VI.[61] The coding region of factor IX's cDNA is indicated in the center and below it the coding and 3'noncoding tail of factor IX's mRNA. The factor IX transcription product is indicated as an elongated rectangle at the bottom. Amino acids of the mature protein are numbered by arabic numerals. Cysteine residues are indicated by an "s," with disulfide bonds tentatively placed. Within the rectangle, solid vertical lines indicate the positions of the seven introns. "Prepro" represents the first 46 amino acids from the point of peptide synthesis initiation to the processing cleavage site; "Gla" is for the domain with gamma-carboxyglutamic acid residues; "EGF" stands for the homologous epidermal growth factor-like regions; "A-P," for the activation peptide which has Asn-linked carbohydrates and the two factor XIa activation cleavage sites (straight arrows and dotted lines); and "tryptic" for the catalytic portion, including the active center Ser, "S."

The last two exons occur at the end of the genomic sequence and are separated by a short intervening sequence. Together they code for the balance of the heavy chain of factor IXa, which shares considerable homology with tryptic serine proteases, particularly those of the clotting system.

The gene structures for prothrombin and protein C are homologous through the third exon, although with somewhat smaller introns (see ref. 8). After the third exon, the prothrombin gene has separate exons coding for two kringle-like structures; this gene is also more variable through the catalytic region, which comprises four separate exons.[13] The gene structure of protein C contains the same number and order of exons as does factor IX. It remains to be determined whether the exons for factors VII and X, and for the homologous regions of the non-protease, vitamin K-dependent proteins S and Z, are similar to those exons within the factor IX and protein C genes. Another distinctive feature of factor IX is the size of the messenger RNA. About half consists of a nontranslated 3' tail that follows the 1.4 kb which are translated.[7]

PROTEIN STRUCTURE AND FUNCTION

Human factor IX has a molecular weight (mol wt) of 54,000 and contains about 17% carbohydrate.[4] It comprises 415 amino acid residues. Their sequence, as dictated by the genomic structure, is illustrated in Fig 2. Beginning with its amino-terminal Tyr, the first 46 residues, as products of the second and third exons, make up the Gla region. Residues 47 through 127 represent the two epidermal growth factor-homologous regions, including several cysteine residues. Between amino acids 128 through 195, as coded for by exon six, are the two arginyl bonds that represent the activation cleavage sites, and the two major carbohydrate side chains. The final 220 residues are products of the last two exons and contain the active site components, the trypsin-like or catalytic portion of factor IXa. The carboxy-terminal residue, No. 415, is Thr.

Gla region. Within the first region are the 12 gamma-carboxy glutamyl residues found in factor IX, beginning with residue 7 and running through 40. These include each site within the region for which a codon specifies Glu. These strongly acidic residues were first identified by Stenflo in bovine prothrombin,[18] where only 10 are found. A vitamin K-dependent carboxylase system associated with the microsomes of hepatocytes is responsible for the posttranslational modification of Glu to Gla.[19] Within the Gla region, human and bovine factor IXs only differ at residues 11, 19, and 37. The two cysteine residues, Nos. 18 and 23, most likely form a disulfide bond, as shown for the homologous sequence in factor X and by the fact that this region of bovine factor IX can be separated without reduction and alkylation after limited proteolytic cleavage.[20]

In prothrombin, the Gla residues account for high-affinity calcium-binding sites. It is not yet known which residues are paired (or perhaps form triplets) three dimensionally. There appear to be several calcium-binding sites in human factor IX,[21,22] and at least two are high affinity.[22] Furthermore, these may be qualitatively distinct.[23] Bovine factors IX[20] and

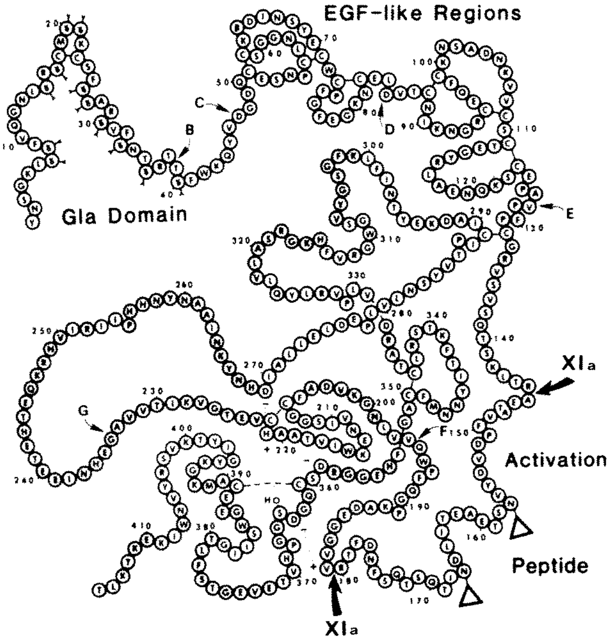

Fig 2. Amino acid sequence of human factor IX. Open circles represent amino acid residues with their standard single-letter abbreviation except that "γ" is for gamma-carboxyglutamic acid and "β" is for beta-hydroxyaspartic acid. Disulfide bonds between cysteine residues (C) are tentatively placed by homology. Residues are numbered from the amino terminal Tyr (Y) through the carboxy terminal Thr (T), residue 415. The locations of introns B through G (see Fig 1) are indicated by the smaller arrows,[8] whereas the larger arrows represent the two cleavage sites for activation by factor XIa.[4] The two Asn-linked carbohydrates in the activation peptide region are indicated by the open triangles. Regions of the heavy chain of factor IXa, which are variable in relation to homologous serine protease sequences,[9] are likely to be represented on the protein's surface and include the following residues: 199-204, 223-268, 301-307, 315-322, 354-358, and 371-380. The catalytic components include: Ser$_{365}$ (–OH), His$_{221}$ (+), and Asp$_{269}$ (–) of the active site; Asp$_{361}$ (–) of the substrate binding pocket; and Asp$_{364}$ (–), which forms an ion pair with the amino terminus of Val$_{181}$ once it has been formed by a specific activation cleavage.

X,[24] like protein C,[25] contain a high-affinity calcium-binding site once the Gla residues are removed after limited chymotryptic cleavage. This occurs at the Phe-Trp bond, residues 41 to 42, in factor IX.[20] However, it is not clear if such a site is expressed on the surface of the native, intact protein. A high-affinity site remains after chemical modification of most of the Gla residues of human factor IX as well.[26] There is indirect evidence that Gla residues function to form calcium bridges with phospholipid monolayers.[27] An alternative explanation is that this region of the vitamin K-dependent factors undergoes a marked conformational change on calcium binding and that the calcium-dependent conformer has phospholipid-binding sites exposed on its surface. This view is supported by studies with metal ion-dependent antibodies.[28] The cooperative effect of calcium binding on factor IX activation is further evidence for a conformational change.[22] If divalent metal ion-dependent conformation is confined to the Gla region, this region would somehow have to influence the activation cleavages and catalytic site of factor IX. Indeed, after chemical modification of the Gla residues, the clotting activity of factor IX is inhibited.[26] It remains possible, however, that other types of calcium-binding sites may exist elsewhere in the molecule, perhaps even in the heavy chain portion of factor IXa. The latter possibility could account for the protective effect of calcium against cleavage of factor IX by thrombin.[29,30]

Growth factor-like regions. The next two regions contain 12 of the 22 cysteine residues found in the entire factor IX molecule. Within the two regions, 12 of these 81 residues (15%) differ between the human and the bovine species. If two sets of three disulfide bonds are arranged according to homology with those of the murine epidermal growth factor, disulfide loops are formed with the bonds between the first and third, second and fourth, and fifth and sixth cysteine residues of each of the two segments.[17] Although the sizes of the two sets of loops differ (eg, residues 74 through 81 *v* 112 through 123, Fig 2), this is also seen when comparing the homologous structures of protein C, in which the first loop contains two additional cysteine residues and a considerably larger sequence.[16] An unusual amino acid, beta hydroxyaspartic acid, at the 64th position for factor IX, is also present in homologous positions in factor X and protein C.[31] It remains unclear whether or not the hydroxylation occurs by the vitamin K-dependent carboxylase system in the liver or imparts any degree of a shared calcium-binding site.[20,24]

In addition to the 10 distinct homologous regions within the murine growth factor gene,[17] similar disulfide-rich structures are present in a diverse array of proteins. These include tissue plasminogen activator where the region is coded for by a separate exon,[32] factor XII,[33] urogastrone (the human equivalent of murine epidermal growth factor), the low-density lipoprotein receptor,[34] and even the early protein of vaccinia virus.[35] Other than the ability of the growth factor hormones to bind to specific cell receptors and stimulate growth, it remains to be shown whether this region of factor IX or the other hemostatic proteins are involved in cellular interactions. It is of interest that prothrombin, being otherwise highly homologous, lacks these two structures but contains instead two kringle-like regions, each coded for by a separate exon.[14] Four kringles are present in plasminogen and include the binding site(s) for fibrin.[36] Kringle-like structures are also found in tissue plasminogen activator[32] and factor XII.[33]

Activation and activation peptide region. The next region to be discussed contains the activation peptide, including the two activation cleavage sites and flanking sequences. Near the amino-terminal end of this region is a cysteine, at position 132. By homology with chymotrypsin, a disulfide bond between this and residue 289 can be tentatively assigned, and thus account for the binding between light and heavy chains of factor IXa. The sites of cleavage by factor XIa[4] (heavy arrows, Fig 2) include an Arg-Ala bond (residues 145 to 146) and an Arg-Val bond (residues 180 to 181). It is of interest that, other than calcium, there are no known cofactors or phospholipid requirements for intrinsic system activation. Phospholipids do enhance the activity of celite-bound factor XIa somewhat.[37] Factor XI can be detected in platelets and factor XIa does bind to the platelet surface.

However, this interaction does not appear to enhance the ability of this enzyme to activate factor IX,[38] and under some conditions, a product of stimulated platelets appears to inhibit activation.[39]

Factor VIIa, with its cofactor tissue factor, also activates factor IX by cleaving the same two bonds as factor XIa in the presence of calcium.[5] From small amounts of intermediates noted on polyacrylamide gel electrophoresis, it appears that the Arg-Ala bond (residues 145 to 146) is most susceptible and is cleaved first.[4,29] A different order of bond cleavage is noted when the coagulant protease from Russell's viper venom is used. This is particularly apparent in bovine factor IX, where the Arg-Val bond (residues 180 to 181) can be cleaved almost exclusively to form factor IXa-alpha, a species with in vitro coagulant activity.[4] From the amounts of intermediate forms of factor IX seen on polyacrylamide gels,† it also appears that the human Arg-Val bond is the most susceptible to cleavage by the venom protease.[29] However, the Arg-Ala bond in human factor IX is more readily cleaved than in bovine factor IX so that the primary product is factor IXa-beta, the enzymatic form that has had both activation cleavages. Human factor IXa-alpha has been isolated and clearly has reduced procoagulant activity when compared with the beta form.[40]

Other proteases can give cleavage patterns similar to those seen on activation, even though they do not specifically cleave arginyl bonds and do not activate factor IX. These include chymotrypsin and elastase.[29,41] An interesting feature of factor IXa generation by contact activation product in vitro is that only partial activation occurs. Indeed, early, partially purified preparations of the factor IX precursor started with either human serum or plasma.[42] The mechanism(s) that inhibits or limits factor IXa formation during intrinsic system clotting of plasma is not known.

Once the two specific arginyl bonds are cleaved, the disulfide-bonded amino-terminal light chain and carboxy-terminal heavy chain migrate as a 20% smaller species than native factor IX on polyacrylamide gels. The noncovalently bound activation peptide can be demonstrated as a broad, lower-mol wt band. The activation peptide contains only 35 amino acids. With its two Asn-linked carbohydrate side chains, it has a mol wt of around 10,000 and reacts with carbohydrate stains. Bovine factor IX has a somewhat larger activation peptide due to a third carbohydrate chain on an Asn equivalent to residue 172.[4] Of interest, 13 of the 35 residues (37%) in the activation peptide differ between human and bovine species as opposed to an 85% identity of residues overall. There are no qualitative differences when activators or substrates among the two species are compared, suggesting that the peptide structure between the cleavage sites has little influence on enzymatic properties. Among other vitamin K-dependent proteases there is little homology in the peptide region; indeed, activated protein C has a peptide of only 12 amino acids without any Asn residues to bind carbohydrate.[16] Along with factor X, protein C circulates predominantly with the equivalent of the Arg-Ala, or first of two activation sites, already cleaved (and missing tri- and di-peptides, respectively), despite their cDNA's specifying single chains.[15-16]

A sensitive assay for the generation of factor IXa has exploited activation peptide formation by using ^{3}H-labeled carbohydrate residues, which become trichloroacetic acid-soluble after cleavage of both activation sites.[43,44] Although such an assay can provide precise and sensitive data for kinetic analyses, it is indirect. Especially in nonisolated systems, other proteases can cleave bonds near those responsible for activation and lead to inactivated species[29] with soluble, labeled carbohydrate peptides.

Heavy chain of factor IXa. As in the three-dimensional structures of trypsin and chymotrypsin, the generation of a free amino group of the hydrophobic Val residue 181 in factor IX, allows ion pair formation with the free carboxyl group of Asp at position 364.[4,9] This would account for activation of the active center Ser, at position 365, by making its hydroxyl group more labile. Catalysis of a peptide bond is facilitated by His at 221 (within a typical disulfide loop toward the amino terminus of the heavy chain) and Asp at 269, which are essential components for the active site. The positively charged side chain of a specific substrate's Arg residue binds ionically in the substrate binding pocket of factor IX, which has its negative charge imparted by the Asp at position 359. Secondary sites for substrate binding to trypsin-like proteases include the Ser at residue 384 and two Glys at positions 386 and 395 in factor IX. The disulfide bond shown between residues 361 and 389 is likewise a common feature.

Factor IXa, a highly restrictive protease, is relatively slow to react with low-mol-wt substrates and inhibitors. Indeed, attempts to find specific substrates with peptide sequences including the bond cleaved in factor X have been unsuccessful.[45] This may in part relate to its need for interaction with a modified form of factor VIII, in addition to phospholipids and calcium, before expressing potent coagulant activity. Thus most assays for factor IXa activity have required the addition of a modified factor VIII and measured, as an end point, the coupled activation or cleavage of factor X.[5,46,47] To probe the active site of factor IXa more directly, a labeled, nonspecific protein inhibitor, antithrombin III, has been used.[29] In the presence of heparin, this forms a stable or covalent-like intermediate with the active form of most coagulant serine proteases, including factor IXa.[48] Specificity was then provided by an insolubilized monoclonal antibody to human factor IX.[3] It was found that factor IX in a complex with the antibody could be activated and bind the labeled antithrombin III to its active site, such that the antibody did not interfere with inhibitor binding. With the labeled inhibitor immunospecific assay, it was possible to show that the activation-like cleavages of factor IX by chymotrypsin and elastase were not associated with generation of an active site; trypsin both partially activated and inactivated factor IX.[29]

It appears that factor IXa can slowly activate factor X,[49] and the basal rate is increased somewhat by phospholipid and calcium.[46,49] With an unmodified form of factor VIII, a lag phase can be seen before generating factor Xa converting activity; the lag is abolished by addition of thrombin-modified factor VIII.[47,50] The latter markedly enhances the activation cleavage of factor X by factor IXa. There is indirect evidence that modified factor VIII interacts with the heavy chain of factor IXa. This evidence is provided by experiments with a monoclonal antibody to factor IX that reacts with the heavy chain portion of reduced factor IXa and interferes with acceleration of factor X cleavage by the modified cofactor.[51] An additional feature of this interaction is that factor IXa markedly stabilizes the activity of thrombin-modified factor VIII to proteolysis by activated protein C.[50]

---

†An inactive intermediate species, consisting of the activation peptide heavy chain (residues 146 through 415) can be seen during activation by factor XIa or factor VIIa tissue factor. A smaller intermediate, corresponding to the light chain activation peptide (residues 1 through 180) is present when activation has been by snake venom protease; the second intermediate is referred to as factor IXa-alpha because it has enzymatic activity.[4,29,40]

In comparing the three-dimensional structures of chymotrypsin and trypsin with the primary sequence data from thrombin and the heavy chains of bovine factors IXa and Xa, Furie et al[9] designated six areas of the heavy chain in which the structure was variable (see Fig 2). In general, these portions of the factor IX molecule can be predicted to be exposed on its surface and correlate with major differences in considering subsequent data on the human and other homologous proteins. For example, the second and largest variable region occurs after the active site His and extends up to the active site Asp (residues 223 through 268). This large loop differs in ten residues in comparing bovine and human species; the former also has an Asn-linked carbohydrate side chain attached to residue 260. From the prevalence of charged residues, especially in the sequence from residues 235 through 249, one would predict strong antigenicity, as shown on the surfaces of other proteins. Considering the heavy chain, complete identity in human and bovine species is found from Asp 359 to the carboxy terminus. The carboxy-terminal tail, from residue 409 through 415, shows less homology among the different hemostatic proteins and may well constitute an additional (seventh) variable region. In factor IX, it contains three positively charged and one negatively charged residues. In contrast, human factor X has an additional 19 amino acids and its bovine counterpart has 24 more residues, including non–Asn-linked carbohydrate.[15,47]

GENETIC POLYMORPHISMS AND SCREENING

Analysis of the gene product for either heterozygote detection or prenatal diagnosis is problematic. Nearly half the women who are obligate heterozygotes for hemophilia B have levels of factor IX clotting activity in their plasmas that are beyond two standard deviations below the normal mean.[52] Determination of factor IX antigen levels can improve precision somewhat over results from clotting activity assays alone, and in some women, circulating abnormal antigen may be detectable to aid in the diagnosis of the heterozygous state.[2] Occasionally, families may be found whose abnormal gene product reacts to polyclonal antibodies but not to a specific monoclonal antibody.[3] Heterozygote detection, however, is confounded by the wide, normal distribution of factor IX levels and random X chromosome inactivation. It is impossible to exclude the carrier state when a woman's factor IX level (ie, the gene product) is within the normal range without additional data from gene analysis.

Prenatal diagnosis has been accomplished in a few cases with an immunoassay based on a specific alloantibody. The first family studied had severe hemophila B, but the mother also had low antigen levels.[53] Variables to consider during mid-gestation, however, are the significant amounts of factor IX in normal amniotic fluid and the low levels in normal fetal plasmas.[54] Due to the difficulties with gene product analysis and the presence of a wide variety of genetic defects, it is more attractive to identify polymorphisms within the factor IX gene and determine how they segregate within specific families. Linkage of a polymorphism to the hemophilic gene can provide a direct approach for both heterozygote detection and prenatal diagnosis.

The first recognized polymorphism within the factor IX gene was the presence of an additional Taq I restriction endonuclease cleavage site occurring just 3' to the fourth exon.[11,55] About 40% of women are heterozygous for this intragenic polymorphism, making it an ideal marker.[55-59] Two additional frequent restriction site polymorphisms have been identified (see Fig 1) such that 65% to 70% of women are heterozygous for one or more of these intragenic sites.[60] By sequencing individual cDNAs, and amino-terminal amino acid sequencing of factor IXa's (including the activation peptide) from different individuals, an additional polymorphic site has been defined.[61] This site corresponds to the codon for residue 148, which is near the amino terminus of the activation peptide. A dimorphism had been suggested by disparate results of the corresponding codon from different genomic libraries. The population frequencies of the polymorhpic residues are not yet available, but the Thr allele appears to be more prevalent.[61] There is no known endonuclease that recognizes this difference, but synthetic oligonucleotide probes could be designed.

At least one polymorphism appears to be present within the heavy chain region of factor IXa. A monoclonal antibody reacting with the heavy chain shows decreased reactivity in plasmas for a significant portion of males, when compared with antigen levels using polyclonal or different monoclonal antibodies.[62] Polymorphism to another monoclonal antibody preparation has also been described.[63] Analysis of polymorphisms of the gene product may, in some cases, be helpful in assessing linkage for detection of heterozygotes. Where applicable, they could avoid the more extensive approach of DNA analysis. It is conceivable that monoclonal antibodies could be made to conjugated synthetic peptides containing, for example, sequences including the respective polymorphic amino acids at residue 148. If these reagents react with native factor IX, they could be used to screen for the polymorphism in the protein.

HEMOPHILIC DEFECTS

Immunologic data suggest that there are a wide variety of genetic defects which account for hemophilia B in different families.[2,3,58,64] Elucidation of the structural bases for these defects in comparison to the functional alterations they incur should provide important data on the mechanisms of activation and action of factors IX and IXa. Data from the several hemophilic defects analyzed to date will be summarized. An additional review of this subject has been written.[65]

Using subgenomic and cDNA probes to factor IX, Giannelli and co-workers looked at the DNA of patients with hemophilia B and circulating inhibitors.[66] Four of the five patients with inhibitors showed gross deletions within their factor IX genomic structures. Curiously, two of them were related but were deleted at different sites. An additional case with an inhibitor was reported to have a partial gene deletion.[67] Another family showed deletion of a 10-kb segment containing the fifth and sixth exons of factor IX, as described by Chen et al.[59] Seven affected members of this family have severe hemophilia B without inhibitors. Therefore, a deletion per se does not mean an inhibitor will occur. Small amounts of a partial gene product with a mol wt of approximately 36,000 were detected in the urines of these patients and of obligate heterozygotes from this family.[68] Antibodies specific for the calcium- dependent conformation of factor IX (ie, its amino terminal end) were also helpful in demonstrating trace levels of antigen in the patients' plasmas. In addition to their interests as a type of genetic defect, partial deletions can serve as markers for heterozygote detection or prenatal diagnosis within the families in which they are found.[59,68]

There have been two hemophilic factor IXs in which an amino acid substitution was identified in unrelated patients with mild to moderately severe hemophilia B. These patients had normal levels of circulating factor IX antigen. The first, factor $IX_{Chapel\ Hill}$, was identified by amino acid sequencing of a tryptic peptide.[69] It was known that this abnormal protein showed a different activation cleavage pattern when electrophoresed on gels, suggesting that only the Arg-Val and not the Arg-Ala activation cleavage site could be hydrolyzed. This was due to an Arg-to-His substitution at residue 145 such that this patient could only form a mutant enzyme that is equivalent to factor IXa-alpha.[40] The second defect has a substitution of Gly for the native Asp at position 47, as determined by sequencing of the cDNA in a patient with factor $IX_{Alabama}$.[70] It is not yet clear how the loss of this negatively charged residue affects the function of factor IX, as there appears to be no difference in calcium binding. Loss of a charged residue does support the concept of a cooperative effect between the light chain and catalytic portions of factor IX. Although earlier studies suggested abnormal binding of factor $IX_{Alabama}$ to phospholipids, on more detailed analysis, binding to lipid vesicles was normal in the presence of calcium.[71] The nucleotide substitution, occurring in a codon that spans the third and fourth exons, could represent an uncommon polymorphism found coincidentally, but it probably accounts for the patient's hemophilia.

Of other abnormal factor IX proteins that have been partially characterized, factor $IX_{Zutphen}$ has an extra peptide that is disulfide bonded.[72] On reduction, the abnormal factor IX is of normal size. The defect is presumably associated with the amino terminal portion of factor IX, where it interferes with the normal calcium-dependent properties in the Gla region of this abnormal protein. It is possible that either of the cysteine residues, at position 18 or 23, has been substituted. This substitution would leave a free sulfhydryl group to bind to another peptide, perhaps even the leader sequence (which contains cysteines at the 19th and 29th residues before the amino terminus). An abnormal factor IX antigen with similarly altered calcium-binding properties appears to result from substitution at the processing protease cleavage site, producing a somewhat larger, albeit single-chained, protein.[73] This defect is referred to as factor $IX_{Cambridge}$.

Several other factor IX proteins have been shown to have either normal or somewhat altered activation cleavage rates.[74,75] Hemophilia B_m is an uncommon type in which there is an associated prolongation of the prothrombin time when ox brain, but not human brain, is used as the source of the thromboplastin.[76] The basis for how the circulating, abnormal factor IX inhibits the extrinsic activation of factor X by factor VIIa when bovine thromboplastin is used remains to be determined.[75,77,78] There appears to be some heterogeneity among different families with the B_m defect, but all patients have had normal levels of circulating factor IX antigen. The molecular defect in a final, isolated factor IX disorder, referred to as hemophilia B Leyden,[79] will be of considerable interest, as it may relate to factors that control the circulating levels of this protein. Only two families have been described and the factor IX levels improve with increasing age, especially after puberty. Congenitally low levels of all four vitamin K-dependent clotting factors have been described.[80-82] These cases are best attributed to abnormalities within the vitamin K-dependent carboxylase and epoxide reductase systems, and the genes for the clotting factors are likely to be normal.

It is anticipated that the list of defined structural defects will proliferate rapidly, given the currently available data on the genomic and amino acid sequences of factor IX. Relation of the molecular defects in the various types of hemophilia B to the specific functional abnormalities they cause will further our knowledge of the role of this protein in the normal mechanisms of blood coagulation. Means to evaluate the potential for its activated form to lead to thrombosis or disseminated intravascular coagulation may then emerge.

ACKNOWLEDGMENT

Drs Earl W. Davie, Kotoku Kurachi, Kenneth J. Smith, and Bruce Furie are thanked for sharing manuscripts and data before publication. Daphne Matlick's steadfast assistance is greatly appreciated.

Production of B Cell Growth Factor(s) by Neoplastic B Cells From Hairy Cell Leukemia Patients

By Richard J. Ford, Deborah Kwok, Jorge Quesada, and C.G. Sahasrabuddhe

Recent studies have shown that normal human T cells contain a high-molecular-weight (mol wt) protein exhibiting B cell growth factor (BCGF) activity. Other studies have shown that virally transformed human B cells also secrete a high-mol-wt BCGF-like molecule in vitro. We have studied neoplastic B cells from patients with untreated hairy cell leukemia (HCL) to ascertain whether such cytoplasmic BCGF activity is present in the tumor cells. Studies on HCL cells from four patients indicated that BCGF-like activity was in fact present in the cytosolic extracts when tested on autochthonous HCL cells as well as on normal BCGF-dependent human B cell lines. Chromatographic analysis indicated that the BCGF activity from HCL cells was similar in mol wt as well as function to the normal T cell-derived cytosolic BCGF activity. These studies suggest that HCL cells contain and, in some cases, secrete a high-mol-wt growth factor that can be autostimulatory and appears to resemble a similar growth factor molecule found in normal human T cells.

© 1986 by Grune & Stratton, Inc.

NORMAL HUMAN B CELL GROWTH has been shown to be dependent on cellular activation by antigen or mitogen,[1,2] followed by the stimulatory action of the T cell lymphokine, B cell growth factor (BCGF).[3,4] Human BCGF has been reported to be heterogeneous with both low (14 to 16 kd)[5,6] and high (50 kd)[7] molecular weight (mol wt) forms described. Recently, a high-mol-wt form (>50 kd) of BCGF has been described in the cytosol of normal human T cells that may represent a precursor molecule for the low-mol-wt secreted form of BCGF.[8] Neoplastic human B cell growth, however, has long been an enigma, since the usual requirements for growth stimulation appear to have been circumvented by apparently autonomous cell growth. We have recently shown, however, that a variety of human non-Hodgkin's lymphomas (NHL) can proliferate in vitro in response to greatly purified BCGF,[9] indicating that these neoplastic B cells have retained the functional capacity to respond to the homologous normal growth factor. We report here that hairy cell leukemia (HCL) cells, a novel type of human B cell neoplasm that expresses the Tac antigen and rearranges Ig genes,[10] contain a high-mol-wt BCGF molecule in the cytoplasm and, in at least some cases, secrete a molecule(s) with BCGF activity. This HCL-associated growth factor can stimulate in vitro cell growth in both autochthonous HCL cells and growth factor (BCGF)-dependent normal human B cell lines.

MATERIALS AND METHODS

Patients. Newly diagnosed untreated patients with HCL were studied at the time of initial presentation. Diagnosis was usually made by bone marrow needle biopsy and aspiration using conventional histopathologic criteria,[11] including cytochemical staining for tartrate-resistant acid phosphatase (TRAP).[12] Four patients with the leukemic form of the disease (WBC > 20,000 μL) with high numbers of HCL cells in the peripheral blood were either leukapheresed or phlebotomized to obtain large numbers of neoplastic B cells.

Cell preparation. Peripheral blood collections from either leukapheresis or venipuncture were separated into peripheral blood mononuclear cells (PBMCs) by Ficoll-Hypaque (FH) density gradient centrifugation. The PBMCs were washed and rosetted using neuraminidase-treated sheep red blood cells (SRBC; E_n) overnight at 4 °C. The rosetted PBMC population was then separated into SRBC rosette positive (E_n^+) or negative (E_n^-) populations on FH gradients. E_n^- cells were then placed onto plastic Petri dishes to remove adherent cells. The nonadherent E_n^- cell population was then washed and prepared for immunophenotyping.

HCL phenotyping. The E_n^- cell population was examined by immunofluorescence with a standard battery of monoclonal antibodies (MAb) for human T and B lymphocytes. The MAb included pan T cell (OKT11, T3; Ortho, Raritan, NJ); pan B cell, B1,[13] B4 (Dr L. Nadler, Dana Farber Cancer Center, Boston); myeloid-monocyte (OKM1; Ortho); and the HCL-associated MAb HC1 and HC2[14] (Dr D. Posnett, Rockefeller University, New York). HCL cases were also studied with the combination of the MAb Leu-14 (pan B) and Leu-M5 (monocyte subset) (kindly provided by Dr N. Warner, Becton Dickinson, Mountain View, Calif), which, when expressed together, can discriminate HCL cells from normal B cells present in a leukemic cell population.[15] The anti-Tac MAb[10] was a gift from Dr T. Waldmann (National Institutes of Health, Bethesda, Md).

In vitro growth factor production. Fresh HCL cells obtained from FH gradients were enriched for B cells by double E_n rosetting, followed by adherence to plastic Petri dishes. The resulting cell populations were ≥90% HCL B cells by immunophenotyping and were ≥90% viable by trypan blue staining. The HCL B cells were then set up in vitro in RPMI 1640 (Irvine, Irvine, Calif) at 2×10^6 cells per milliliter in 1% fetal calf serum (FCS; Hyclone, Logan, Utah) or 1% bovine serum albumin (BSA; Sigma Chemical Co, St Louis) and incubated at 37 °C for 24 hours in 5% CO_2 atmosphere. The culture supernatants were collected by pelleting the cells in a refrigerated centrifuge at 800 g for ten minutes and were tested for BCGF activity on growth factor-dependent human B cell lines[16] or on autochthonous HCL B cells.

Cytosolic BCGF activity from HCL cells. Cytoplasmic extracts from neoplastic HCL B cells were prepared and assayed for by the methods described by Sahasrabuddhe et al[8] for normal human T lymphocytes. Briefly, the tumor cells were pelleted and resuspended in hypotonic buffer containing 20 mmol/L HEPES (pH 7.5), 1.4 mmol/L Mg $(AC)_2$, 3.6 mmol/L $CaCl_2$, and 2 mmol/L 2-mercaptoethanol. The tumor cells were lysed with 40 strokes in a glass homogenizer and the lysate was centrifuged at 1,500 g for ten minutes to remove nuclei. The supernatant was centrifuged at 10,000 g for ten minutes to remove mitochondria and then ultracentrifuged at 100,000 g for 90 minutes to remove cell membranes and

to obtain soluble cytosolic proteins in the supernatant. The cytosolic extract was concentrated by lyophilization and either assayed for BCGF activity or fractionated on a Sephacryl 200 (Pharmacia Fine Chemicals, Piscataway, NJ) gel filtration column.

Microassays for in vitro growth factor activity. Growth factor preparations from neoplastic human HCL B cells were assayed either on continuous BCGF-dependent human B cell lines[16] or on the autochthonous tumor cells from which the growth factor was derived. The normal B cell lines were maintained in log phase growth in the presence of RPMI 1640 medium, 3% (vol/vol) heat-inactivated FCS, and greatly purified BCGF preparations.[3] For the assay, B cells (≥95% sIg, B1$^+$) cultured for 72 hours were washed extensively in medium (four to five times) to remove any residual bound growth factor. The assays were performed in triplicate in flat-bottom 96-microwell plates (Corning Glass, Corning, NY), using a total of 1.0 to 1.5 × 10^4 cells per well in a final volume of 200 μL. The assays in which the target cells were exposed to serial dilutions of growth factor preparations were performed in RPMI 1640 supplemented with 2% (vol/vol) FCS for 48 hours. Sixteen hours before harvest the cells were labeled with 0.5 μCi (6 Ci/mmol) of ^{3}H-thymidine (^{3}H-Tdr; New England Nuclear, Boston) and harvested, using an automated micro cell harvester (Brandel, Palo Alto, Calif). ^{3}H-Tdr incorporation was determined using a liquid scintillation spectrometer (Beckman LS-8100, Palo Alto, Calif).

Tumor cell growth factor activity was assayed on freshly prepared or cryopreserved immunophenotyped HCL B cells after E_n rosetting and adherent cell removal. The HCL cells were plated at an initial cell density of 1 × 10^5 cells per well. The tumor growth factor preparations were then titrated into the wells at a final volume of 0.2 mL per well. The microwell plates were incubated for 72 hours at 37 °C in a 5% CO_2 atmosphere. The cells were then labeled with ^{3}H-Tdr for the last 16 hours of incubation period and harvested as described.

Gel filtration chromatography. Tumor cell supernatants and cytosolic extracts from HCL cells were chromatographed on a Sephacryl 200 column (2 × 100 cm) that had been calibrated with a variety of mol wt protein markers. The column was eluted in phosphate-buffered saline (PBS), 10 mmol/L phosphate, pH 7.0, with 5-mL aliquots collected per fraction. The proliferative activity of the eluted samples was then tested on growth factor-dependent cell lines in 72-hour ^{3}H-Tdr incorporation assays as described.

RESULTS

Characterization of HCL cells. Four patients with the clinical and pathologic diagnosis of HCL were studied. All had the leukemic form of the disease (>20,000 WBC/μL; ≥80% leukemic cells by morphology), and the cells studied were collected either by leukapheresis or by venipuncture. The tumor cells were enriched for by double E_n rosetting, followed by plastic adherence. The E_n negative cell populations obtained appeared to contain only HCL cells by morphological criteria and were ≥90% TRAP positive. Table 1 shows the phenotypic characterization of the HCL cells, which demonstrate that the tumor cells had standard B cell membrane markers, including cell surface immunoglobulin (sIg) and the characteristic pan B cell antigen recognized by the MAb B1. In addition, however, the myeloid-monocytic MAb, OKM1, and Leu-M5 were also present on most, if not all, of the neoplastic cells. The HCL cell population also contained the Tac antigen, which is associated with the receptor to human T cell growth factor but has also been found on some normal human B cells. The combination of the pan B cell MAb, Leu-14 labeled with fluorescein (FITC), and Leu-M5 labeled with phycoerythrin (PE) stained HCL cells simultaneously, while single-stained cells identified occasional residual normal B cells or monocytes, respectively. Further analysis by sIg light chain typing for assessing monoclonality of B cells and nonspecific esterase for monocytes indicated that ≤5% of the total HCL cell population represented these contaminating cell populations.

Table 1. Cell Surface Phenotype of HCL Patients

HCL Patient	sIg*	κ/λ	B1	Leu-14/M5†	HC2	Tac	OKM1	T_{11}
1	94	93/2	86	91	87	73	84	3
2	96	98/1	92	93	90	81	86	2
3	88	80/3	93	90	90	85	81	4
4	89	90/2	83	78	88	75	80	3

PBMCs from untreated HCL patients were separated on FH gradients and then rosetted with neuraminidase-treated SRBC (E_n) overnight at 4 °C. The E_n negative cells were then depleted of adherent cells and immunophenotyped for cell surface antigens.

*E_n-HCL cells were assayed using mouse monoclonal antibodies by indirect immunofluorescence with appropriate controls. The number shown represents the percentage of positive cells staining with each of the designated reagents.

†Leu-14, Leu-M5 double-staining percentage with FITC and phycoerythrin conjugated reagents, respectively.

Production of growth factor activity by HCL cells. HCL cell populations were set up for in vitro culture in either low-serum (1%) or serum-free (1% BSA) conditions and incubated for 24 hours at 37 °C in a 5% CO_2 atmosphere. At the termination of the culture period, the cells were centrifuged and the culture supernatants were removed. Cell viability at this time was ≥80%. The supernatants were then either frozen for future studies or used immediately in in vitro proliferative assays using either long-term growth factor-dependent human B cell lines or autochthonous HCL cells that had been maintained in vitro for 24 to 36 hours. Table 2 shows a representative example of these studies, where it can be seen that the populations of HCL B cells

Table 2. HCL Culture Supernatant Autostimulatory Activity

Target Cells	Bkgd	SN (1% BSA)			
		5%	10%	20%	30%
HCL Patient 1	132	990	1263	1725	2752
HCL Patient 2	156	680	1560	2580	ND
BD23	480	981	1867	4332	10175
BDk9	320	684	1424	4427	9564

HCL supernatants (SN) were generated at a final density of 2 × 10^6 cells per milliliter from E rosette and adherent cell-depleted tumor cell populations that were cultured for 24 hours in RPMI 1640 + 1% BSA. Two SN from each patient were obtained and tested. HCL cells are the B cells isolated from the patient's peripheral blood lymphocytes by negative selection procedure described in Materials and Methods. BD23 and BDk9 are BCGF-dependent normal B cell lines. HCL cells (1 × 10^5, >95% viable) or normal B cells (1.5 × 10^4, BD23 or BDk9 cell line) were cultured in microwells for 48 hours with varying dilutions of HCL-derived supernatants. Microwell cultures were labeled with 1 μCi of ^{3}H-Tdr for the final 24 hours of the 72-hour culture period. Results are expressed as mean cpm of triplicate assays. Standard errors were less than 10%.

release a soluble factor into culture supernatants that stimulate proliferation in both long-term human B cell lines as well as autochthonous, freshly obtained HCL cells in vitro. The release of the growth factor appears to be spontaneous in all patients studied, although the amount of activity varies somewhat from patient to patient. Growth factor activity does not seem to require lectin stimulation. In fact, lectin (PHA, protein A) stimulation does not augment the release of the growth factor. Also, it was found that the BCGF cytoplasmic activity from normal T cells would also stimulate ^{3}H-Tdr incorporation in the HCL cells (data not shown).

High-mol-wt growth factor activity in the cytosol of HCL cells. Normal human T lymphocytes have been shown to contain a high-mol-wt (>60 kd) BCGF activity in their cytosol, which may be a precursor molecule for the low-mol-wt (14 to 16 kd) secreted form of human BCGF. We were interested to ascertain whether neoplastic human B cells, such as HCL, contained such a molecule. For these studies, we purified populations of HCL cells as before and prepared cytoplasmic extract to obtain a cytosolic protein fraction. The cytosolic fraction was assayed on long-term human B cell lines as before to determine whether BCGF activity was present. Table 3 shows examples of the cytosolic fraction from two patients' HCL B cells that were positive when tested for BCGF activity on long-term BCGF-dependent cell lines. This BCGF activity was also found to titrate in a dose–response manner similar to the cytosolic BCGF obtained from normal human PBMCs. The cytoplasmic BCGF activity from normal PBMCs has been previously shown to be exclusively present in T lymphocytes.[8]

Chromatographic characterization of cytosolic BCGF activity from HCL cells. Because we had identified BCGF activity in the cytosolic compartment of HCL B cells, it was of interest to compare this factor with the cytosolic fractions obtained from lectin-activated normal human PBMCs. Therefore, the concentrated cytosolic extract from HCL B cells was chromatographed on a Sephacryl 200 column that had been calibrated with a variety of standard protein mol wt markers. Figure 1 shows the elution profile of the cytosolic and secreted BCGF-like activity from HCL B cells as compared with the similar cytosolic activity obtained from normal human T lymphocytes. It can be observed that the BCGF activities from both sources eluted from the column in a similar manner, suggesting that the growth factor activities obtained may share biochemical as well as functional similarities.

Table 3. Cytoplasmic BCGF Activity From HCL Cells

Target Cells	Cytoplasmic Growth Factor Added to Cultures (% vol/vol)	Source of Cytoplasmic Growth Factor ^{3}H-Tdr Incorporation (cpm)		
		Normal PBMCs	HCL Patient 1	HCL Patient 2
BD23 B cells	0*	198	166	198
	0.2	3738†	3740	1620
	0.6	7796	4720	2640
	1.2	9489	3936	1322
	2.5	8962	5396	3633
	3.0	ND	6794	4890
	10.0	ND	8512	ND
	20.0	ND	9486	ND

Target cells for evaluating cytoplasmic BCGF activity consisted of long-term BCGF-dependent B cell lines used at 13,000 cells per well.

*Cytoplasmic growth factor activity obtained from fractionated E_n-negative HCL that were >90% TRAP, sIg, κ, B1, Leu-14/M5, Tac positive.

†Mean cpm of triplicate assays of 72-hour cultures, labeled for final 24 hours with 1 μCi ^{3}H-Tdr. Standard errors were less than 10%.

DISCUSSION

The control of cell growth in malignant human B cells is an area of considerable interest and importance to the immunobiology of these neoplasms as well as to their clinical behavior. The description and characterization of human B cell growth factor for normal B cells[17] has greatly increased our understanding of how normal B cell proliferation is

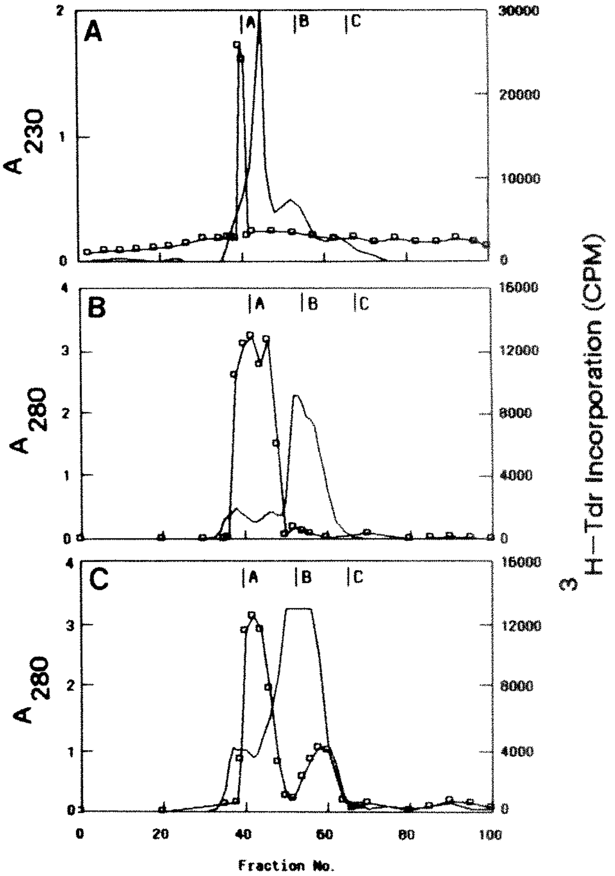

Fig 1. Composite figure showing Sephacryl 200 chromatograms of HCL cell culture supernatants (C), cytosol from purified HCL cells (B) as compared with the cytosolic BCGF activity obtained from normal human PBMCs (A). Proliferative activity (^{3}H-Tdr incorporation) was assayed on growth factor-dependent human B cell lines (□) at a final concentration of 10% (vol/vol). Absorbance at A_{230} or A_{280} is shown in the solid lines without symbols. Mol wt markers (Bio-Rad, Richmond, Calif) used for calibrating the gel column were (a) gamma globulin (158 kd), (b) ovalbumin (44 kd), and (c) myoglobin (17 kd).

regulated through the secretion of soluble factors.[18,19] Our recent studies have shown that neoplastic human B cells from a variety of non-Hodgkin's lymphomas and chronic leukemias can be stimulated to proliferate in vitro with BCGF.[9] These studies suggest that normal homologous (ie, B cell lineage) growth factor(s) can at least stimulate neoplastic B cell growth in vitro experimentally. The secretion of BCGF under the usual immunologic circumstances appears to be a tightly regulated control mechanism, similar to interleukin 2 regulation that is mediated through various types of accessory cell interactions and their soluble cytokine products.[20,21] It would therefore seem unlikely that the reactive (normal) accessory cells usually present either in neoplastic lymphoid lesions or in the peripheral blood in the chronic B cell leukemic state could account for the necessary BCGF activity, which is presumably needed to drive the neoplastic proliferative process. A likely source for such growth factor activity might then be the neoplastic B cells themselves. Since ample experimental precedence for autocrine growth factor mechanism(s) in tumor cells exists[22,23] and recent studies have indicated that Epstein-Barr virus-transformed human B cells can secrete a BCGF-like factor,[24-26] the prediction would be that at least some type of growth factor activity should be present in the culture supernatants if the tumor cells can in fact secrete the factor. Similarly, such a factor(s) could be found in the cytoplasm of the tumor cell itself, as is the case in the normal T lymphocyte.

The important recent observation that a high-mol-wt BCGF molecule is present in the cytoplasm of normal T cells, possibly representing a precursor molecule for the low-mol-wt secreted form of BCGF,[8] suggested the possibility that a similar type of system might occur in neoplastic B cells. We have subsequently observed that both secreted and cytoplasmic factors with BCGF activity could be demonstrated in fresh HCL cells. The cytoplasmic BCGF from the HCL cells appears to be similar, if not identical, to that found in normal human T cells, but the HCL BCGF activity does not show as sharp a peak after elution from Sephacryl 200 gel filtration chromatography. Also, the elution profile appears to indicate that the mol wt of both the normal PBMCs as well as the HCL cytoplasmic growth factor activity is greater than 100,000 when compared with the elution of the mol wt markers used to calibrate the column. However, recent studies indicate that when the normal cytoplasmic BCGF is purified to homogeneity, it has a mol wt of approximately 60,000, as determined more accurately by sodium dodecyl sulfate-polyacrylamide gel electrophoresis.[27] The elution profiles shown in Fig 1 compare the normal and HCL cytoplasmic growth factors, but this technique gives only the general range of mol wt. When taking these considerations into account, we believe that the actual mol wt of the HCL cytoplasmic growth factor will correspond to that found in normal PBMCs.

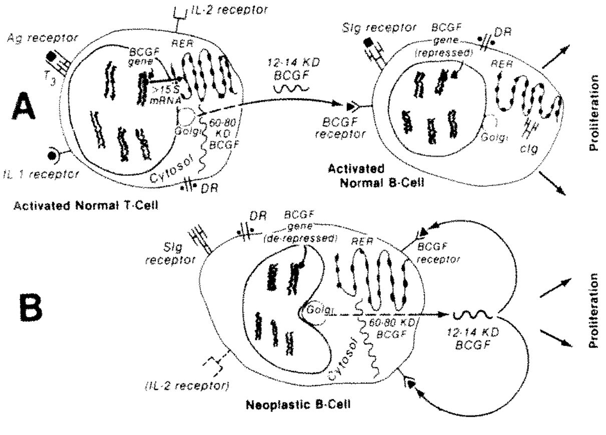

Fig 2. Comparison of a hypothetical scheme for the control of neoplastic B (HCL) cell growth (B) with a schematic representation of current concepts involved in the control of proliferation of normal human B cells (A). Neoplastic B cell growth is hypothesized to result from the expression of the gene for BCGF, which is not usually expressed in normal B cells, resulting in an autocrine loop mechanism where the neoplastic B cell can produce its own growth factor. The tumor cell, which constitutively expresses the receptor for the growth factor, then can respond to the autochthonous factor by proliferating.

These findings suggest an autocrine model of neoplastic B cell proliferation exemplified by HCL, which is shown in Fig 2, and contrasted to a current conceptual model for the control of normal B cell proliferation.[8] In this model, neoplastic B cells (HCL) contain a high-mol-wt BCGF molecule in their cytoplasm that is secreted, in most cases, as either a high- or a low-mol-wt BCGF molecule. This model implies that the neoplastic B cells possess functional receptors for the BCGF molecule that do not require in vitro activation in freshly prepared tumor cells. This type of autocrine stimulation also implies that the gene for BCGF, which does not appear to be expressed in normal, nonvirally transformed B cells, is expressed in neoplastic B cells such as HCL. Neoplastic B cell proliferation driven by an autostimulatory growth factor should circumvent the control mechanisms regulating normal B cell proliferation. This model appears to be consistent with the growth kinetics of most B cell neoplasms and suggests a number of interesting possible approaches to the control of neoplastic B cell growth in the future.

ACKNOWLEDGMENT

We thank the Clinical Immunology staff of M.D. Anderson Hospital for their cooperation with the patient studies, and Tammy Trlicek and Elvia Mercado for manuscript preparation. We also acknowledge the excellent technical assistance of Linda Yoshimura.

Defective T Cell Responsiveness in Chronic Lymphocytic Leukemia: Analysis of Activation Events

By Neil E. Kay and Manuel E. Kaplan

Chronic lymphocytic leukemia (CLL) is a B cell disorder in which major T cell proliferative defects are present. We investigated the nature of this deficit by studying several parameters known to be crucial in normal T cell proliferative response to mitogen. Purified peripheral blood T cells from B-CLL patients were analyzed for the presence of T3 antigen. We observed that CLL T cells have a direct correlation between levels of T3 membrane antigen and proliferative response to mitogen. The appearance of activation antigens (transferrin, HLA-DR, and interleukin 2 [IL 2] receptor) was normal in CLL T cells post-mitogen exposure. Despite the normal presentation of IL 2 receptor on CLL T cell membrane, there was decreased production of IL 2 by CLL patients (*v* controls) (39.6 ± 10.2 cells per milliliter *v* 64.6 ± 11.0 cells per milliliter). Finally, we were able partially, but not fully, to reconstitute CLL T proliferative response to mitogen by adding purified exogenous IL 2. These findings suggest that CLL T cells have multiple defects that may impact on their proliferative potential. Further insight into these deficits may result in strategies that will facilitate immunologic restoration in T cells of these patients.

© 1986 by Grune & Stratton, Inc.

CHRONIC LYMPHOCYTIC LEUKEMIA (CLL), typically a monoclonal B cell malignancy, is frequently accompanied by various peripheral blood T cell abnormalities.[1-8] These include T cell lymphocytosis,[1,2] low T4-T8 ratios with inadequate helper activity for B cell proliferation and immunoglobulin synthesis,[3-6] and depressed to absent natural killer activity[7,8] and autologous mixed lymphocyte reactivity.[9] In addition, variably decreased responses to mitogen-induced (phytohemagglutinin [PHA] or concanavalin A [Con A]) proliferation have been reported by several investigators.[10-12] We have recently described a subgroup of CLL patients in whom only a minority of erythrocyte rosette positive (ER$^+$) peripheral blood T cells reacted with monoclonal antibodies to T3,[12] a 20- to 25-kd membrane antigen normally present on mature T cells and medullary thymocytes.[13,14] In contrast to other CLL patients whose T3-ER$^+$ ratios were more normal (≥ 0.6), T cells from this CLL subgroup exhibited markedly defective responses to PHA and Con A. The T3 antigen is now known to be required for normal T cell activation.[15,16] Consequently, we have attempted to better define the mechanisms of abnormal T cell responsiveness to lectins in this group of CLL patients by enzymatically exposing additional membrane T3, studying the appearance of membrane activation antigens, measuring interleukin 2 (IL 2) production, and enhancing proliferative responses with exogenous normal IL 2.

MATERIALS AND METHODS

Eleven B-CLL patients and 11 normal donors, matched for age and sex, were studied. CLL patients were staged according to the method of Rai: stages 0 to 1, five patients; stage 2, four patients, and stage 4, two patients. No patient had received chemotherapy within four weeks of study.

Preparation of ER$^+$ cells. T cells were isolated by virtue of their ability to rosette with sheep erythrocyte (SRBC). Peripheral blood mononuclear cells were prepared from heparinized venous blood by Ficoll-Hypaque centrifugation, resuspended in RPMI 1640 containing 10% fetal bovine serum (FBS), and depleted of adherent cells by incubation in sterile plastic Petri dishes for one hour. Nonadherent cells were incubated with SRBC pretreated with AET (2-aminoisoethylisothyronium hydrobromide), and the ER$^+$ cells were pelleted by centrifugation through Ficoll-Hypaque. ER$^+$ lymphocytes were freed of SRBC by brief hypotonic lysis in distilled water. This procedure gave a purity 98% or greater for ER$^+$ lymphocytes (measured by rerosetting with SRBC-AET).

Treatment of ER$^+$ lymphocytes with neuraminidase. ER$^+$ cells (2×10^7/mL) suspended in PBS were incubated with *Vibrio cholerae* neuraminidase (50 U/mL) (Behring Diagnostics, Somerville, NJ) at 37 °C for 30 minutes with shaking. The cells were then washed repeatedly with PBS to remove excess enzyme and resuspended in RPMI-10% FBS.

Detection of T cell membrane antigens. The following monoclonal antibodies were used to detect surface membrane antigens of ER$^+$ lymphocytes: OKT3, TAC (anti-IL 2 receptor), OKT9 (anti-transferrin receptor), and 5/12 (anti-IA). (Monoclonal antibodies OKT3 and OKT9 were purchased from Ortho Laboratories, Raritan, NJ; TAC was generously provided by Dr Thomas Waldmann, National Institutes of Health; 5/12 was a generous gift of Dr Soldano Ferrone, New York Medical College, NY.) ER$^+$ cells (1×10^6/mL) in RPMI-10% FBS were incubated (4 °C, 30 minutes) with 20 to 50 μL of an appropriate dilution of monoclonal antibody. The cells were then washed twice with RPMI-10% FBS and incubated for an additional hour with 100 μL of a 1:40 dilution of fluoresceinated goat F(ab)$'_2$ antimouse immunoglobulin (Dako, Burlingame, Calif). After thorough washing, the cells were examined with a Zeiss fluorescence microscope equipped with epifluorescence filters.

PHA-induced mitogenesis. ER$^+$ cells (2×10^5) isolated from controls or CLL patients were mixed in microtiter wells (Linbro, Hamden, Conn) with 1 μg/mL purified PHA (PHA-16, Burroughs Wellcome, Triangle Park, NC). After 72 hours of incubation (37 °C, 5% CO_2), 2 μCi of tritiated thymidine (^{3}[H]Tdr) (New England Nuclear, Boston) was added. After an additional 24-hour incubation, cells were harvested and radioactivity measured by liquid scintillation spectrometry. Results were calculated and expressed as mean ± standard deviation of the mean (SEM). In some studies, exogenous IL 2 was added simultaneously with PHA. The IL 2 was derived from normal, PHA-stimulated lymphocytes (see below), or recombinant IL 2 (generously provided by Cetus Corporation, Emeryville, Calif) was used. IL 2 concentrations ranging from 0.1% to 20% were used.

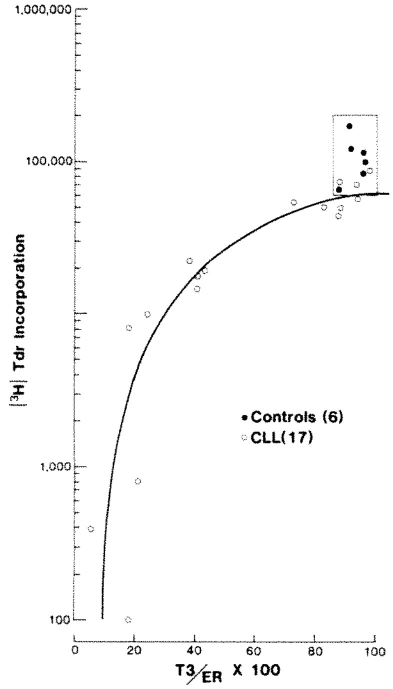

Fig 1. Relationship between T cell proliferation and T3 membrane antigen. The T3-ER$^+$ ratios of CLL (O) (n = 17) or control (●) (n = 6) subject lymphocytes are plotted *v* the ^{3}[H]Tdr incorporation of the same lymphocytes PHA-induced ^{3}[H]Tdr incorporation.

IL 2 production and quantitation. Lymphocytes (10^7/mL, control and CLL) in RPMI–10% FBS were incubated with 1 μg/mL PHA for 24 hours (37 °C, 5% CO_2). PHA–lymphocyte-conditioned media (PHA–LCM) supernatants were harvested and stored at −70 °C until being assayed for IL 2 activities. IL 2 measurements were performed by a modification of the method of Gillis et al,[17] using the CTLL-20, IL 2-dependent cell line.[18] CTLL-20 cells were maintained in RPMI–5% human serum and were fed every other day with 10% to 20% of a murine IL 2 source (spleen LCM derived from MLC). CTLL-20 cells were washed twice to remove residual IL 2, distributed into microtiter wells (0.5 to 1.0 × 10^4 CTLL per well), and supplemented with various dilutions of normal or CLL PHA–LCM. Dilutions of a standard human IL 2 source were invariably included. After 24-hour incubation, the cells were pulsed for six hours with 2 μCi ^{3}[H]Tdr. A log probit plot of the standard IL 2 source was used to quantify IL 2 activities of the unknown PHA–LCM.

RESULTS

Relationship between CLL T cell proliferation and membrane T3 antigen. We have previously reported that CLL T cell populations containing low T3-ER$^+$ ratios exhibit subnormal mitogenic responses to PHA.[12] The present studies confirm our previous findings and demonstrate a high degree of correlation between T3-ER$^+$ ratios and levels of ^{3}[H]Tdr incorporation (Fig 1). Ratios $\geq$0.6 were invariably associated with more normal proliferative responses. Patients with ratios $\leq$0.3 (n = 5) had significantly less proliferation than patients with ratios $\geq$0.6 ($P < 0.5$; n = 10).

In an effort to augment the defective responses, we treated CLL cell populations having low T3-ER$^+$ ratios with neuraminidase, which, as we have previously shown, enhances their T3 antigen expression.[12] Although neuraminidase treatment markedly increased the percentages of T3-positive cells from 38% to 78%, no significant improvement in PHA-induced ^{3}[H]Tdr incorporation resulted.

Appearance of membrane activation antigens in CLL and control T cells. Figure 2 summarizes the kinetics of appearance of various activation antigens after exposure of CLL and control T cells to PHA. During the first 48 hours, T9, TAC, and IA increased at similar rates in patient and control cells; thereafter, T9 and TAC gradually declined. In contrast, IA expression of control, but not of CLL, cells continued to increase between 48 and 72 hours. The rate and degree of expression of activation antigens bore no relationship to T3-ER$^+$ ratios or to the magnitude of ^{3}[H]Tdr incorporation. The standard error of the mean for all points plotted in Fig 2 ranged from 4% to 10%.

IL 2 production by CLL and control T cells. CLL T cells were found to elaborate approximately 55% of control IL 2 activities in response to PHA stimulation. Table 1 summarizes the relationship of CLL ER$^+$ lymphocytes to their membrane T3 presentation and PHA-induced IL 2 production and ^{3}[H]Tdr incorporation (Table 1). In general, the lower the T3-ER$^+$ ratio, the lower the thymidine incorpora-

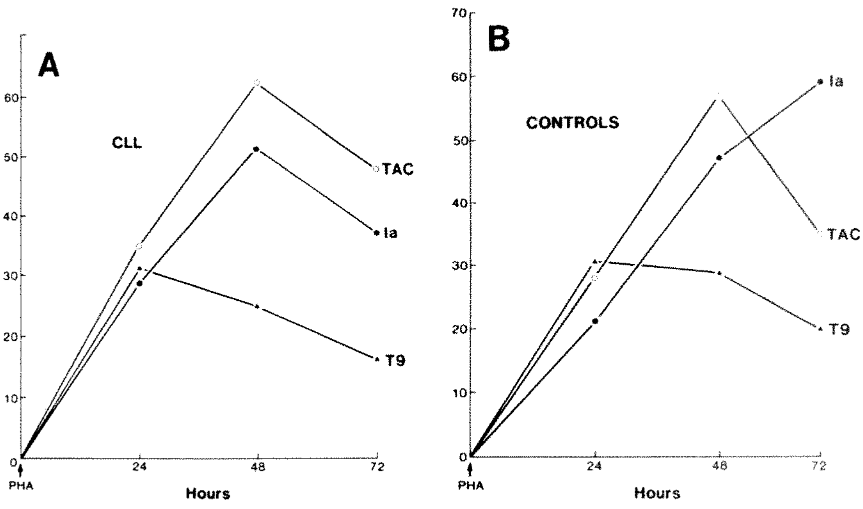

Fig 2. Sequential analysis of (A) CLL (n = 7) or (B) control (n = 7) ER$^+$ lymphocyte membrane activation and post-PHA exposure. The mean percentage of each activation antigen (TAC = O, Ia = ●, transferrin = ▲ T9) is plotted over a 72-hour incubation period.

Table 1. CLL ER$^+$ Lymphocytes in Relationship to Their T3 Membrane Antigen, IL2 Production, and PHA-induced ^{3}[H]Tdr Incorporation

	ER$^+$ Lymphocytes		
Group	T3 Positive (%)	IL 2 Production (μ/mL)	^{3}[H]Tdr (cpm/10^5 cells)
I (0%–30%, n = 4)	13.5 ± 2.9	31.5 ± 27.8	$2.9 \pm 1.8 \times 10^{-2}$
II (30%–60%, n = 4)	40.8 ± 1.0	32.8 ± 26.5	$18.5 \pm 1.4 \times 10^{-3}$
III (>60%, n = 6)	87.5 ± 3.6	45.8 ± 11.7	$59.3 \pm 6.8 \times 10^{-3}$
Control (n = 11)	92.5 ± 2.6	64.6 ± 11.0	$109.8 \pm 15.8 \times 10^{-3}$

CLL ER$^+$ lymphocyte groups were arbitrarily divided into three groups: I, ER$^+$ lymphocytes that were 0% to 30% reactive with OKT3; II, ER$^+$ lymphocytes 30% to 60% reactive with OKT3; and III, ER$^+$ lymphocytes >60% reactive with OKT3.

tion. IL 2 production was somewhat lower in ER$^+$ lymphocytes with <60% T3 reactive cells, but the difference was not statistically significant.

Enhancement of mitogenesis by exogenous IL 2. Because after PHA stimulation CLL T cells developed various activation antigens normally but produced diminished amounts of IL 2, we attempted to improve their mitogenic responsiveness by supplementing them with exogenous IL 2 (Fig 3). Addition of 10% IL 2 improved somewhat, but did not normalize, the proliferative responses of CLL T cells to PHA. The greatest degrees of improvement were seen in CLL patients exhibiting low T3-ER$^+$ ratios. Addition of higher concentrations of IL 2, or repetitive supplementation with IL 2 over the 72-hour incubation period, failed to further enhance T cell proliferative responses.

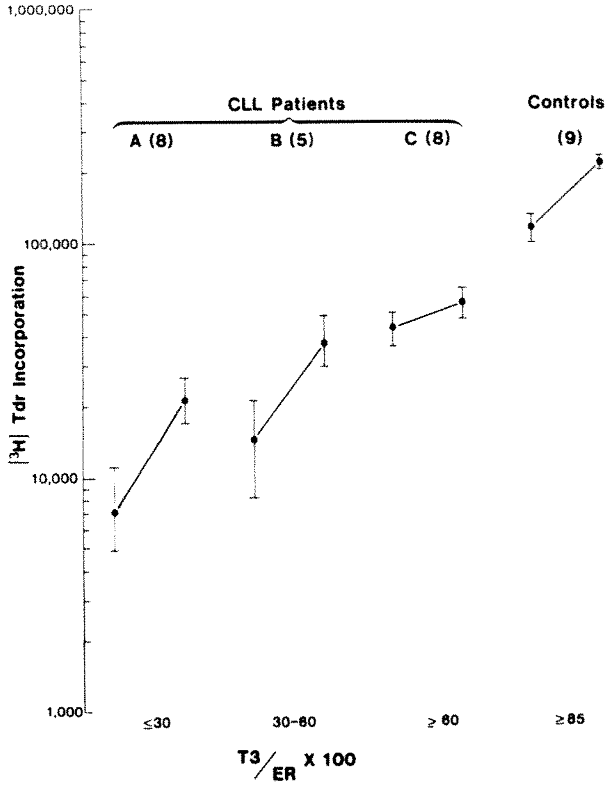

Fig 3. ^{3}[H]Tdr (mean ± SEM) incorporation of ER$^+$ lymphocytes pre- and post-exposure to 10% IL 2 are plotted for CLL and controls. CLL patients were subdivided into three groups based on the percentage of ER$^+$ cells that are T3 reactive: A = 0% to 30% T3$^+$, B = 30% to 60% T3$^+$, and C = >60% T3$^+$.

DISCUSSION

Activation of normal T cells may be arbitrarily conceptualized as occurring in three sequential stages: (1) engagement of Ti, the T cell antigen receptor intimately associated with T3[19]; (2) development of multiple membrane activation antigens, including T9 (transferrin receptor), TAC (the receptor for IL 2); the T cell growth factor, and IA[20]; (3) synthesis and elaboration of IL 2, which combines with TAC to trigger mitogenesis.[21] In an effort to better understand the mechanisms of the defective proliferative responses of CLL T cells to PHA and other immunologic stimuli, we have examined each of the stages for possible abnormalities. We have previously reported that the peripheral blood of CLL patients showing exceedingly poor responses to PHA contain high percentages of ER$^+$ cells that poorly express T3 membrane antigen.[12] T3 is known to be required for normal T cell proliferative responses and development of cytotoxic effector cell functions.[15,16] The studies described confirm our previous findings and emphasize the close relationship between T3 expression and mitogenic responsiveness (Fig 1). Although treatment of these low T3-ER$^+$ cell populations with neuraminidase significantly improved their T3 expression, no parallel enhancement of mitogenic responsiveness occurred. The T3 antigen comprises several membrane glycoproteins containing different numbers of sialic acid residues.[14] Because neuraminidase treatment exposes additional T3 antigenic sites without enhancing mitogenic responsiveness, additional yet undetected defects may be present within the CLL T3 complex. Alternatively, other abnormalities may be responsible for defective cell proliferation.

To investigate other possible abnormalities, we studied the appearance of various membrane activation antigens induced by PHA stimulation of CLL T cells. Surprisingly, the rates of appearance of T9, TAC, and IA were entirely normal, unrelated to the degree of T3 expression or to the mitogenic responsiveness of the individual cell populations. Although we detected significantly diminished IL 2 activity in PHA–CLL T cell conditioned media, no relationship was observed between the degree of abnormality in IL 2 elaboration, T3-ER$^+$ ratios, and mitogenic responsiveness. Moreover, only minimal improvement in the proliferative responses of these cells to PHA could be induced by addition of exogenous IL 2, despite the presence of apparently normal numbers of IL 2 receptors. These findings suggest that receptor binding of IL 2 may be defective or that even more distal defects in the mitogenic sequence may be present, ie, in the generation of the recently described inducible cytoplasmic factor that initiates DNA replication.[22]

Thus it appears that CLL T cells exhibit multiple abnormalities that may relate to their diminished proliferative potential. Continued exploration of the molecular nature of these abnormalities should yield insights that may permit immunologic reconstitution of patients with this disorder.

The Detection of Specific Antibody Formation to Recall Antigens After Human Bone Marrow Transplantation

By Lawrence G. Lum, Nathan A. Munn, Moses S. Schanfield, and Rainer Storb

The results of this study show that donor-derived immunity can be detected and persists in long-term survivors with and without chronic graft-*v*-host disease (GVHD) after human marrow grafting. Seventy-one marrow recipients (60 long-term and 11 short-term survivors) were studied for the presence of specific serum IgG antibodies to tetanus toxoid (TT), and 46 marrow recipients (35 long-term and 11 short-term) were tested for antibodies to diphtheria toxoid (DT) and measles virus after marrow grafting using an enzyme-linked immunosorbent assay. Of the 60 long-term survivors, 31 were healthy and 29 had chronic GVHD. None of the recipients were immunized to the test antigens postgrafting. Most long-term healthy recipients exhibited antibody titers to the recall test antigens, whereas only a minority of those with chronic GVHD had antibody titers to recall antigens. In healthy long-term recipients (≥ one year postgrafting) whose donors were immune to the test antigens, 25 of 31 had titers to TT, 11 of 17 had titers to DT, and 12 of 20 had titers to measles. In recipients with C-GVHD, 13 of 29 had titers to TT, six of 15 had titers to DT, and six of 15 had titers to measles virus. Within 100 days postgrafting, 11 of 11 had anti-TT titers, ten of ten had anti-DT titers, and seven of eight had antimeasles virus titers.

© 1986 by Grune & Stratton, Inc.

EARLY EXPERIMENTS in mice and rats showed that the infusion of bone marrow, spleen cells, lymph node cells, or thymus cells from an immune donor could transfer specific immune reactivity.[1-4] However, such adoptive transfer experiments showed only transient antibody-forming ability in the recipients. Studies in the canine marrow-grafting model showed that certain canine marrow recipients exhibited distemper titers after DLA-matched marrow transplantation without posttransplant immunizations to distemper.[5] Because both the marrow donors and the recipients were immunized to distemper before marrow transplantation, the interpretation of such data was difficult.

Despite a large body of literature on immune reconstitution after human marrow transplantation (reviewed in ref. 6), information on the transfer of specific immunity from donors to recipients after human marrow transplantation is scarce. Earlier studies examined recipient's delayed hypersensitivity responses to recall antigens and antibody responses to keyhole limpet hemocyanin, bacteriophage ΦX174, and pneumococcal polysaccharide antigens.[7-10] These studies showed primary and secondary responses to neoantigens by one to two years postgrafting. These studies did not address the question of transfer of specific antibody-forming ability from marrow donors to marrow recipients. One early report used keyhole limpet hemocyanin immunization of a twin donor as an immunologic marker for bone marrow graft acceptance in an identical twin transplanted for acute lymphocytic leukemia.[11]

This study investigates the transfer of specific antibody-forming ability from the marrow donor to the marrow recipient. The investigation shows that there is rapid development of this ability by recipient lymphocytes without postgrafting immunization to tetanus toxoid (TT), diphtheria toxoid (DT), and measles virus when the donor lymphocytes were immune to these antigens. The donor-derived immunity can be detected and persists in long-term survivors with and without chronic graft-*v*-host disease (GVHD). Such data on these common recall antigens will facilitate the development of immunization recommendations for the management of transplant recipients.

MATERIALS AND METHODS

Subjects. Seventy-one patients transplanted for hematologic malignancy or aplastic anemia were studied for the presence of serum antibody titers. Sixty-five received allogeneic transplants from HLA-identical siblings, five received syngeneic transplants, and one received an HLA-haploidentical transplant. In this study there were 14 chronic myelogenous leukemia, 15 acute lymphocytic leukemia, 27 acute nonlymphocytic leukemia, two Hodgkin's lymphoma, one erythroleukemia, one lymphatic leukemia, and 11 aplastic anemia patients. Patients with hematologic malignancies were conditioned with cyclophosphamide and total body irradiation[12-14] and patients with aplastic anemia were conditioned only with cyclophosphamide.[15] Methotrexate, cyclosporine, or both were used as posttransplant prophylaxis for GVHD.[16] Cyclosporine or antithymocyte globulin was used for the treatment of established acute GVHD, while others received steroids or a combination of the above.

Twenty-nine long-term survivors (>100 days postgrafting) developed chronic GVHD, and 20 of these were treated with either prednisone alone or in combination with cyclophosphamide, procarbazine, or azathioprine. Thirty-one healthy long-term survivors were studied. Seventy-one patients were studied pretransplant and posttransplant for IgG anti-TT titers, and 46 of these were also studied for IgG anti-DT and IgG antimeasles titers. None of the recipients were immunized to the test antigens posttransplant. None of the long-term survivors who were studied at ≥ one year postgrafting had received blood products in the six-month interval before testing. The 60 long-term survivors were studied betwen 320 and 3,295 days postgrafting. Twenty-five of these were studied longer than two years postgrafting. The bone marrow donors did not receive booster immunizations to the test antigens in the two-year period before marrow donation.

Serum collection. Serum samples were collected from marrow transplant recipients and their donors pretransplant and on the days posttransplant as indicated in Figs 1 through 3.

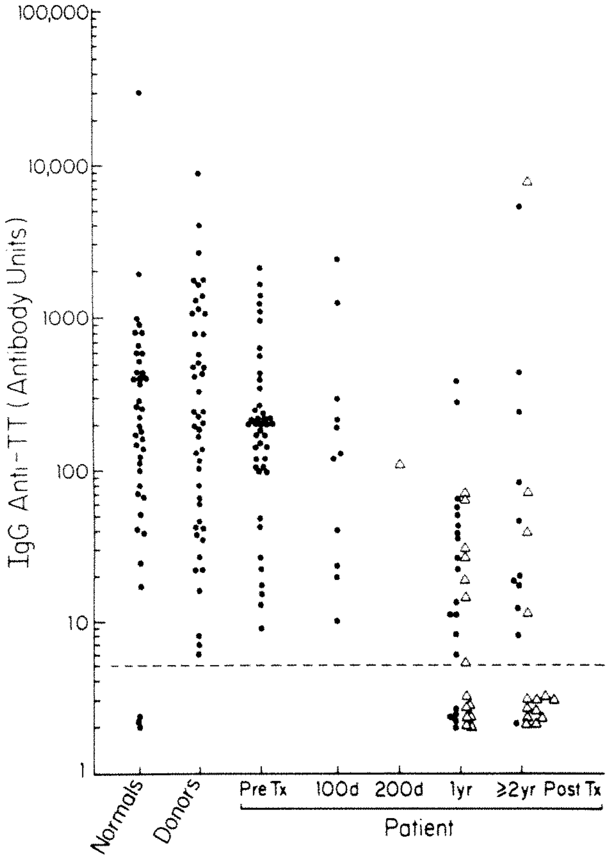

Fig 1. The IgG anti-TT titers (AU) are summarized for the normal controls, the donors, the pretransplant host, and the titers of the marrow-graft recipients with (Δ) and without (●) chronic GVHD. Each recipient was studied once postgrafting. Points below the dashed line were considered negative titers.

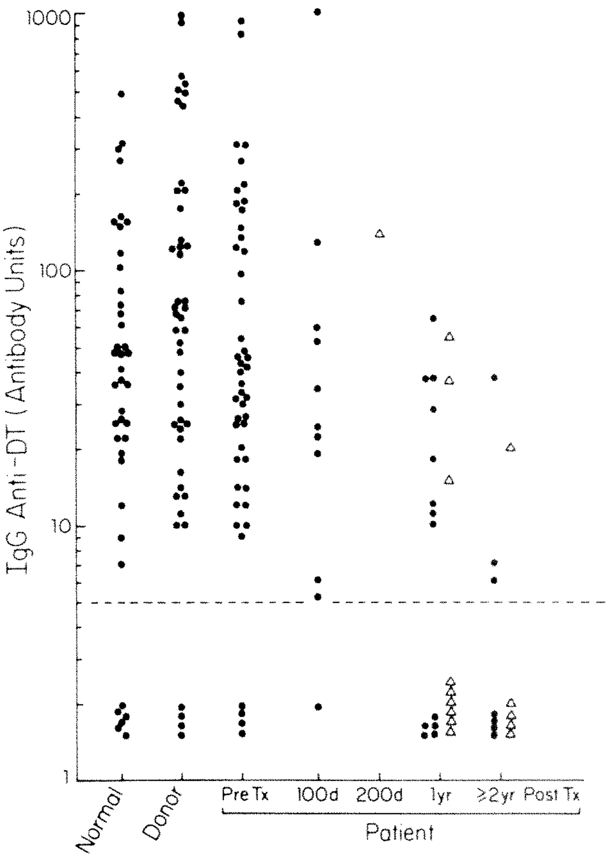

Fig 2. The IgG anti-DT titers (AU) are summarized for the normal controls, the donors, the pretransplant host, and the titers of the marrow-graft recipients with (Δ) and without (●) chronic GVHD. Each recipient was studied once postgrafting. Points below the dashed line were considered negative titers.

Cytogenetics. When there were differences in cytogenetic sex markers, all but one of the recipients (30 out of 31) had lymphocytes of donor origin. One individual was a mixed chimera. Cytogenetics on the remaining donor–recipient pairs were not informative.

Enzyme-linked immunosorbent assay (ELISA). Serum IgG titers to TT, DT, and measles were measured using an ELISA modified from that described.[17,18] Briefly, NUNC EIA plates (NUNC, Copenhagen, Denmark) were coated with 100 μL of either 1.0 Lf/mL TT or 2.0 Lf/mL DT (lots No. LP463P and DT254PD, respectively, Commonwealth of Massachusetts Department of Public Health, Boston), or a 1:100 dilution of measles antigen (lot No. X30-364, M.A. Bioproducts, Los Angeles) diluted in Tris buffer, pH 9.6, 15 to 18 hours at 37 °C.

Plates were washed in phosphate-buffered saline (PBS) containing 0.05% polyoxyethylene sorbitan monolaurate (Tween 20, Sigma Chemical Co, St Louis) and blocked for one hour at 37 °C with 10% bovine serum albumin in PBS. Plates were then washed in PBS–Tween solution and stored at −20 °C. Plates were warmed and washed in PBS–Tween solution before use.

Anti-TT IgG standard was prepared from high-titer anti-TT human serum, depleted of non-IgG protein by QAE-A50 Sephadex (Pharmacia, Piscataway, NJ) and affinity purified over TT-linked Sepharose 4B (Pharmacia). The amount of specific IgG anti-TT antibody in the standard was directly calibrated in a polyclonal IgG ELISA using goat antihuman IgG specific underlayer (capture) antibody (Tago, Burlingame, Calif) and a peroxidase-conjugated goat antihuman IgG developer.[18]

The antibody concentrations of unknown serum samples diluted on a $\log_{10}$ basis for IgG anti-TT, IgG anti-DT, and IgG antimeasles were interpolated directly from the affinity-purified IgG anti-TT standard.

The optical density reading of the last positive serum dilution was compared with the linear portion of the linear regression line drawn from the human IgG anti-TT standard.[18] Only optical density values between 0.1 and 1.0 were used for interpolation. Known dilutions of the anti-TT standard were placed into triplicate wells coated with TT on each plate. Therefore, IgG antibody units (AU) relative to the IgG anti-TT standard could be interpolated directly from the optical densities of the IgG anti-TT standard on each plate for DT and measles virus titers with 1 AU ≈ dilution of serum × 1 ng/mL estimated by direct comparison with the IgG anti-TT standard. The goat antihuman IgG-specific peroxidase-conjugated developer would bind only with IgG bound to the specific antigen on the plate. The IgG-specific developer did not detect IgA, IgM, or IgE standards at the upper concentration of 20 ng/mL.

One hundred microliters of diluted serum was added to each microtiter well. All dilutions were done in 10% fetal calf serum in balanced salt solution. The plates were incubated for two hours at 37 °C and washed with PBS–Tween solution. One hundred microliters of peroxidase-conjugated goat anti-human IgG antibody (lot No 901401, Tago) diluted 1:1,500 in 10 mmol/L phosphate buffer was

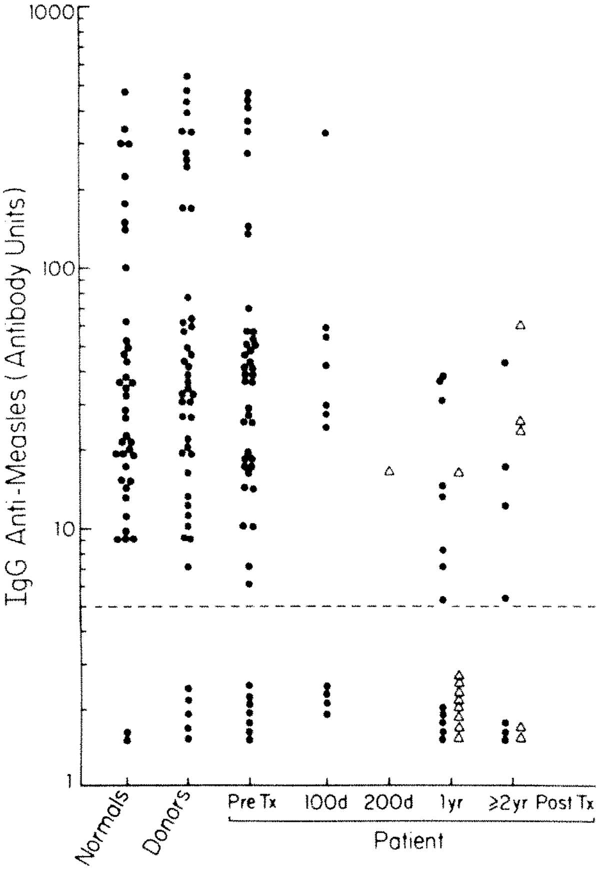

Fig 3. **The IgG antimeasles titers (AU) for the normal controls, the donors, the pretransplant host, and the titers of the marrow-graft recipients with (Δ) and without (●) chronic GVHD. Each recipient was studied once postgrafting. Points below the dashed line were considered negative titers.**

added to each well, incubated at 37 °C for one hour, and washed with PBS–Tween. One hundred microliters of a 1.0 mg/mL solution of 2,2′-azinodi-(3-ethylbenzthiazoline sulfonic acid) in citrate buffer, pH 4, plus 0.03% H_2O_2 was added to all wells. The optical density was read at 414 nm after 30 minutes.

An optical density equal to 0.1 at a 1:1,000 serum dilution or above was considered a positive titer. Backgrounds were infrequently present at serum dilutions ≤1:100. Serum from agammaglobulinemic patients and from normal individuals known by history to be negative for a specific antigen had an optical density <0.1 at a serum dilution of 1:100.

Normal range for antibody titers. Forty normal individuals and 71 marrow donors ranging in age from 3 to 50 years served as controls to determine the normal interval. Normal range was defined as the interval above which 95% of the immune normal individuals studied had specific IgG titers to TT, DT, and measles virus. Titers below this interval were considered negative.

Statistics. For all analyses, the antibody titers were compared in a Wilcoxon rank sum test (two-tailed). For DT and measles titers, four and five patients, respectively, had donors who did not have titers and these were excluded from the statistical analysis, although they are shown in the figures. All donors had TT titers.

RESULTS

Antibody titers to TT. Figure 1 summarizes the serum IgG anti-TT titers in AU for the normal controls, the marrow donors, and the marrow recipients pretransplant and posttransplant. Each marrow graft recipient was studied only once after marrow grafting. The study was not sequential. Figure 1 shows IgG anti-TT titers on healthy recipients and those with chronic GVHD. All of their donors had normal IgG anti-TT titers. Between one and two years, 15 of 20 (75%) healthy survivors and seven of 14 (50%) recipients with chronic GVHD had anti-TT titers. After two years, ten of 11 (91%) healthy survivors and five of 15 (33%) recipients with chronic GVHD had anti-TT titers. Statistical compari-

Table 1. Analysis of Patient–Donor Pairs Pretransplant and Posttransplant

Immune Status of Patient–Donor Pairs	IgG Anti-TT Ab (n = 50)		IgG Anti-DT Ab (n = 45)		IgG Anti-measles Ab (n = 45)	
	Healthy	C-GVHD	Healthy	C-GVHD	Healthy	C-GVHD
Informative for specific immunity						
Donor (+)						
Patient pre-tx (−)	0	0	0	1	2	0
Patient post-tx (+)						
Donor (−)						
Patient pre-tx (+)	0	0	2	0	1	0
Patient post-tx (−)						
Donor (+)						
Patient pre-tx (+)	31	10	21	5	17	5
Patient post-tx (+)						
Noninformative for specific immunity						
Donor (−)						
Patient pre-tx (−)	0	0	2	0	4	0
Patient post-tx (−)						
Donor (+)						
Patient pre-tx (+)	2	7	6	7	5	10
Patient post-tx (−)						
Donor (+)						
Patient pre-tx (−)	0	0	0	1	1	0
Patient post-tx (−)						

A (+) signifies a titer ≥1:1,000, a (−) signifies a titer <1:1,000 by ELISA. The combination of donor (−), patient pre-tx (+), and patient post-tx (+) did not occur. Pre-tx, pretransplant; post-tx, posttransplant.

sons between the healthy long-term chimeras and the marrow-graft recipients with chronic GVHD show that the healthy chimeras had significantly higher IgG anti-TT titers than their counterparts with chronic GVHD ($P < .006$).

Antibody titers to DT. Figure 2 summarizes the serum IgG anti-DT in AU for the normal controls, the marrow donors, and the marrow recipients pretransplant and posttransplant. Four donors did not have detectable IgG anti-DT antibody titers. Each transplant recipient was studied once postgrafting. Ten of ten (100%) recipients 100 days postgrafting had anti-DT titers in the normal range. Between one and two years, eight of 11 (73%) healthy survivors and three of nine (33%) recipients with chronic GVHD had anti-DT titers. After two years, three of six (50%) healthy survivors and two of six (33%) recipients with chronic GVHD had anti-DT titers. There was no statistical difference between recipients with and without chronic GVHD.

Antibody titers to measles virus. Figure 3 summarizes the serum IgG antimeasles virus in AU for the normal controls, the marrow donors, and the marrow recipients pretransplant and posttransplant. Five donors did not have detectable IgG antimeasles virus antibody titers. Each transplant recipient was studied once postgrafting. Seven of eight (88%) recipients had antibody titers to measles virus 100 days postgrafting. Eight of 12 (67%) healthy survivors and one of nine (11%) recipients with chronic GVHD had antimeasles virus titers between one and two years after marrow grafting. After two years, four of six (67%) healthy survivors and four of six (67%) recipients with chronic GVHD had antimeasles virus titers. There was no statistical difference between the healthy long-term survivors and those with chronic GVHD.

Chronological recovery of specific antibody titers in a single patient. One recipient (UPN 1353) with chronic GVHD was studied 791 and 1,061 days postgrafting. She received an HLA-identical, mixed lymphocyte culture nonreactive marrow graft from her brother. The recipient had a measles virus titer of 23 AU/mL and had no titers to TT or DT 791 days postgrafting. By 1,061 days postgrafting, the recipient had 211 AU of IgG antimeasles virus, 13 AU of IgG anti-TT, and 27 AU of IgG anti-DT. Cytogenetic sex markers on both occasions showed the lymphocytes to be of donor (XY) origin. Both donor and recipient were immune to all three antigens pretransplant.

Evidence for transfer of specific antibody immunoreactivity in donor–recipient pairs. Data in Table 1 summarize the titer data for all recipients. Table 1 contains both informative and noninformative data; the data shown in boldfaced type are informative. Table 2 gives the specific details of the six informative cases in boldfaced type selected from Table 1. In three of the six cases shown, donors had measurable antibodies to measles or diphtheria antigens, while recipients were negative before transplantation. When tested 80 to 465 days after transplantation, all three recipients made antibodies presumably through donor-derived cells. Conversely, three donors did not make antibodies to measles or diphtheria antigens, while their respective recipients did when tested before grafting. When tested 385 to 616 days after grafting, all three recipients failed to make antibody, signifying the disappearance of host-derived immunity and the establishment of donor cells not previously exposed to these antigens.

Table 2. Evidence for Transfer of Specific Immunity

UPN	Antigen	Donor Titer	Recipient Titers Pregrafting	Recipient Titers Postgrafting	Day of Study
2268	Measles	30	—	24	80
1668	Measles	38	—	30	465
1854	Measles	—	38	—	385
1782	Diphtheria	539	—	15	318
1823	Diphtheria	—	18	—	426
1502	Diphtheria	—	33	—	616

The specific antibody titers are estimated antibody units (AU) as described in Materials and Methods. Specific antibody titers to measles or DT ≤5.0 AU were considered negative. The last column shows the number of days postgrafting that serum was obtained. A minus (−) indicates a titer below the normal range.

DISCUSSION

The assumption that antibody production to diphtheria and measles beyond day 100 after allogeneic bone marrow transplantation represents immunity transferred with donor cells is based on at least four pieces of evidence: (1) recipients with antibody production after bone marrow transplantation had donors immune to the same antigens pretransplant; (2) when donors failed to make antibodies, recipients were found to be negative after bone marrow transplantation, including recipients who made antibodies before bone marrow transplantation; (3) immunoglobulin allotype production of host type ceases by day 120 after bone marrow transplantation in 97% of the recipients[19]; and (4) in recipients with ABO-incompatible transplants, host-type isohemagglutinin production ceases at a median of 40 days after bone marrow transplantation, although immunity may persist in isolated cases for up to five months postgrafting.[9]

The majority of long-term healthy recipients developed serum IgG antibody titers to TT, DT, and measles. It is not likely that these findings represent environmental re-immunization, particularly in the short period of time postgrafting. Although one study has shown mixed chimerism in the lymphocytes of two marrow graft recipients and host-type RBC markers more than one year postgrafting,[20] it is unlikely that host-type B cells could account for the normal levels of IgG anti-TT, anti-DT, and anti-measles antibodies in so many marrow-graft recipients. Marrow-graft recipients who did not develop titers to TT, DT, or measles virus posttransplant show that the transfused antibody did not contribute to antibody titers postgrafting.

Most marrow-graft recipients with chronic GVHD failed to develop antibody titers to recall antigens. The reasons for failure to develop specific antibody titers in this group of recipients are not clear. Both chronic GVHD and the treatment thereof with immunosuppressive regimens could suppress the development of antibody-forming cells.

Immunoglobulin allotyping confirmed donor-origin Ig allotypes in two donor–recipient pairs who were confirmed to be IgG allotype mismatched; however, we were not technically able to type affinity-purified IgG anti-TT–specific antibodies from these individuals to show allotype transfer of IgG anti-TT directly.

Mature T and B cells transferred in the marrow inoculum were probably responsible for producing specific antibodies. Recent studies using a TT-stimulated specific antibody synthesis showed that purified T cells from long-term marrow-graft recipients can help IgG anti-TT antibody production in vitro after stimulation with TT in cocultures with immune donor B cells[21] and that recipient B cells can produce IgG anti-TT in the presence of donor helper T cells. Our findings are consistent with a recent study using human bone marrow obtained after primary and booster immunizations with TT that showed B cells could spontaneously synthesize IgG anti-TT and could be stimulated with pokeweed mitogen to produce IgG anti-TT.[22] The presence of marrow mononuclear cells capable of producing IgG anti-TT in immune subjects and the presence of antigen-specific lymphocytes in the peripheral blood of long-term marrow recipients support the contention that mononuclear cells in the marrow inoculum are responsible for the transfer of immunity.

Persistent antigen in the reticuloendothelial system did not play a major role in the re-presentation of antigen to newly maturing cells from the transplanted marrow, since immune recipients who received marrow grafts from nonimmune donors did not develop specific antibody titers.

In the first 100 days, persistent differentiated host B cells and passive transfusion of antibody may contribute to detectable antibody. However, the levels of specific antibody detected at 100 days postgrafting suggest a major contribution by B cell engraftment, since it would be nearly impossible to attain normal antibody levels from packed red cells and/or platelet transfusions.

Insufficient numbers of donor–recipient pairs prevented an analysis of factors that might influence the formation of specific antibody, such as the relationship between identical twin transplants and healthy allogeneic recipients, the preparative regimen, the pretransplant diagnosis, and the type of posttransplant immunosuppression.

These results help to explain why more transplant recipients do not develop life-threatening infections with diseases against which their donors had been immunized. In more than 1,500 patients transplanted in our center, only one case of measles has occurred. A recipient developed measles after being exposed to his donor who developed measles postgrafting. In this case, the donor was probably not immune to measles pretransplant. These clinical observations suggest that many recipients are indeed protected by specific antibodies to recall antigens produced by donor-derived B cells. If transfer of antibody-forming capability to viruses occurred as satisfactorily as transfer of specific antibody-forming capabilities to measles, immunity to mumps, rubella, and polio may be transferred equally well. However, only followup on marrow recipients will determine whether their circulating levels of specific antibody are protective.

The proportion of marrow-graft recipients developing specific antibody titers or the levels of specific antibody might be increased by booster immunizations to the donor pretransplant. Healthy recipients or recipients with chronic GVHD who have not developed specific antibody titers by one year after transplant should be immunized with appropriate vaccines and evaluated for specific antibody titers. Those with chronic GVHD may not respond to immunizations and healthy individuals may respond to recall antigens as if there were "neoantigen" antigens.

Anti-CALLA Antibodies Identify Unique Antigens on Lymphoid Cells and Granulocytes

By John M. Pesando, Patricia Hoffman, Nancy Martin, and Ted Conrad

The common acute lymphoblastic leukemia antigen (CALLA) is a 100-kd surface glycoprotein that is present on normal and malignant lymphoid cells. It is a useful marker for distinguishing between clinically important types of acute leukemia. Anti-CALLA monoclonal antibodies (MoAb) also react with mature myeloid cells (granulocytes), where they identify an antigen having a similar molecular weight (mol wt). We now report that the antigens detected by anti-CALLA MoAb on human lymphoid and myeloid cells differ in their behavior and chemistry. Surface-labeling studies indicate that the antigen on lymphoid cells has a mol wt of approximately 100 kd v 110 kd for that on granulocytes. When cells are metabolically labeled with ^{35}S-methionine, differences in the mol wt of these antigens are again observed. Unlike the lymphoid antigen, expression of that on purified granulocytes is not modulated by incubation with specific antibody. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis analysis of proteolytic digests of the two antigens fails to clarify their chemical relationship. Thus the antigens detected on these two cell types may share an epitope(s) but be chemically distinct, or CALLA may exist in distinct forms and behave differently on lymphoid cells and granulocytes.
© 1986 by Grune & Stratton, Inc.

CALLA IS A 100-kd surface glycoprotein expressed on malignant cells of approximately 70% of patients with acute lymphoblastic leukemia (ALL) and on rare lymphoid cells in normal bone marrow.[1-3] Its expression is reduced or modulated by incubation of cells with specific antibody.[4-7] CALLA is not expressed by leukemic cells of patients with acute nonlymphocytic leukemia (ANL) or of most patients with T cell ALL, making it a useful marker for diagnosing clinically important subtypes of acute leukemia. Its function remains unknown.

On normal cells, CALLA appears to be preferentially expressed on immature, rather than mature, lymphocytes. In contrast, anti-CALLA monoclonal antibodies (MoAb) react with mature (granulocytes) rather than immature myeloid cells, where they identify a 110-kd surface protein.[8-10] Study of the effects of anti-CALLA MoAb on the specialized functions of granulocytes might therefore clarify the role of this antigen. However, the results of our present serologic and immune precipitation studies indicate significant differences in the antigens identified on myeloid and lymphoid cells.

MATERIALS AND METHODS

Antibodies. Five CALLA-specific MoAb were used (anti-CALLA-1 (J5), anti-CALLA-4, anti-CALLA-5, anti-CALLA-6, and anti-CALLA-7).[10,11] Hybridomas producing these MoAb were raised by immunization of BALB/c mice with CALLA-positive malignant cells. Anti-CALLA-1 was raised to leukemic cells from a patient with ALL,[11] anti-CALLA-4, -5, and -6 to the ALL cell line Laz 221,[10] and anti-CALLA-7 to the Burkitts cell line Ramos. All identify a similar 100-kd surface glycoprotein and show identical reactivity patterns with cells from a panel of 38 acute leukemias and 32 hematopoietic cell lines. Modulation of CALLA by our initial anti-CALLA MoAb (J5) inhibits binding of the four other CALLA-specific MoAb.[4,5] MoAb were obtained from either cell culture supernates or ascites from tumor-bearing mice. They were ultracentrifuged and filtered before use.

Cells. Normal granulocytes were isolated by density gradient centrifugation on Ficoll-Diatrizoate (LSM, Litton Bionetics, Kensington, Md).[10] Wright-Giemsa staining confirmed that cell purity was greater than 90%. Viability was greater than 95%, as measured by trypan blue exclusion. Laz 221[12] and NALM-6[13] are CALLA-positive ALL cell lines.

Immunofluorescence analysis. Binding of MoAb to target cell populations at 4 °C was determined using a standard indirect immunofluorescence assay[2] and monitored on the fluorescence-activated cell sorter (FACS IV, Becton Dickinson, Mountain View, Calif), with fluorescence displayed in the logarithmic mode. Before analysis, cells were suspended in RPMI 1640 containing 5% human AB serum to block Fc receptor sites. MoAb were used at a 1:100 dilution of ascites fluid to ensure antibody excess.

Antigenic modulation. Modulation of CALLA by specific MoAb was performed as described previously.[4,5] Filter-sterilized anti-CALLA or isotype-matched control MoAb (100 μg/mL per 1×10^6 cells) was added to appropriate cultures, followed by incubation at 37 °C for 16 hours. The extent of modulation was monitored by indirect immunofluorescence using the FACS.

Identification of antigens. Cell surface radiolabeling with ^{125}I and immune precipitation of detergent-solubilized cell extracts were performed using standard methods.[5] Antigens were resolved by electrophoresis on a 7% to 20% gradient sodium dodecyl sulfate-polyacrylamide slab gel (SDS-PAGE) and visualized by autoradiography. A ratio of 1 mCi of ^{125}I to 50×10^6 cells was used. For metabolic labeling, freshly purified granulocytes or NALM-6 cells were incubated with 1 mCi of ^{35}S-methionine per 50×10^6 cells for 16 hours at 37 °C in methionine-free media.[6] Detergent-solubilized cell extracts were purified by affinity chromatography on a lentil lectin column. Retained material was used in immune precipitation experiments following elution with alpha-methyl-D-mannoside.

Peptide analysis. Proteolytic digests of radiolabeled antigens identified by anti-CALLA MoAb on NALM-6 cells and granulocytes were compared using a modification of the method of Cleveland et al.[14] Nonreducing sample buffer was added to pellets of iodinated antigens purified by immune precipitation, followed by a three-minute incubation at 110 °C. Immediately before electrophoresis, samples were treated with fresh solutions of individual proteases in the same sample buffer or sham treated for 30 minutes, all at 22 °C. Proteolysis was terminated by addition of 2-mercaptoethanol to a final concentration of 5%, followed by a repeat three-minute

incubation at 110 °C. Three proteases were used: trypsin, chymotrypsin, and papain (Sigma Chemical Co, St Louis).

RESULTS

Incubation of purified leukemic cells with specific antibody at 37 °C produces a cell population with a reduced capacity to bind anti-CALLA MoAb (antigenic modulation or, more correctly, epitope modulation) (Fig 1). In contrast, incubation of purified granulocytes from humans (nine donors) or from *Macaca fascicularis* (three animals) with anti-CALLA MoAb under identical conditions does not modulate expression of the detected epitope. Titration studies indicate that supernates from treated samples of both ALL cells and granulocytes contain comparable amounts of anti-CALLA MoAb, thus ruling out selective proteolysis of MoAb by the granulocyte sample. It is of note that the granulocyte antigen can be induced to modulate by anti-CALLA MoAb in the presence of monocytes (data not shown). This phenomenon has been observed with other antigens.[15,16]

Anti-CALLA MoAb identify a 100-kd glycoprotein on lymphoid cells metabolically labeled with ^{35}S-methionine or surface labeled with ^{125}I. In contrast, the molecular weight (mol wt) of the antigen identified by anti-CALLA MoAb on granulocytes from the same individual varies with the method of labeling used. Metabolic labeling with ^{35}S-methionine yields a 90-kd antigen, whereas surface labeling with ^{125}I identifies one of 110 kd (Figs 2 and 3). Although the mol wt of the antigen detected in biosynthetically labeled granulocyte preparations suggests that it is not made by contaminating lymphoid cells, it does not permit unequivocal identification of p90 as CALLA. Because p90 is not found on granulocytes that are surface labeled with ^{125}I, it may not be present or exposed on the cell surface. Further work is necessary to study these two forms of the granulocyte antigen.

To assess the homology of their polypeptide structures, proteolytic digests of the antigens identified by anti-CALLA-1 MoAb on iodinated human granulocytes and ALL cells were analyzed by SDS-PAGE and visualized by autoradiography (Fig 3). Proteolysis of the antigen isolated from ALL cells produces multiple novel lower mol wt species. Why several of the cleavage products generated by these three proteases have similar mol wt (most notably those at approximately 75, 55, and 45 kd) is unclear.

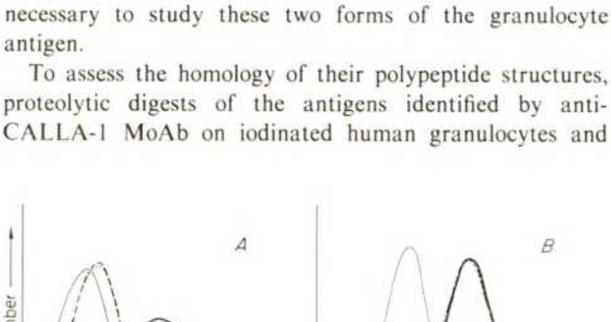

Fig 1. **Modulation of CALLA. Cells from the ALL cell line Laz 221 or purified granulocytes were incubated with comparable amounts of anti-CALLA-1 or an isotype-matched control MoAb for 16 hours at 37 °C (Panels A and B, respectively). They were then assayed for their ability to bind control or anti-CALLA-1 MoAb. Samples are as follows: control and anti-CALLA-1 MoAb on sham-modulated cells (thin and thick solid curves, respectively); control and anti-CALLA-1 MoAb on anti-CALLA-1 treated cells (thin and thick dashed curves, respectively). The ability to bind anti-CALLA-1 MoAb after incubation at 37 °C with the same reagent is decreased on ALL cells but not on granulocytes.**

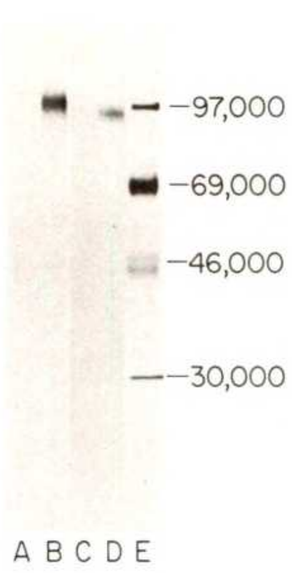

Fig 2. **Antigens detected by anti-CALLA-1 MoAb on ALL cells and granulocytes metabolically labeled with ^{35}S-methionine. Samples are as follows: A, control MoAb on NALM-6 cells; B, anti-CALLA-1 MoAb on NALM-6 cells; C, control MoAb on granulocytes; D, anti-CALLA-1 MoAb on granulocytes; and E, ^{14}C-labeled mol wt standards. Markers were purchased from New England Nuclear (Boston) and include phosphorylase B (97 kd), albumin (69 kd), ovalbumin (46 kd), and carbonic anhydrase (30 kd).**

Proteolysis of the granulocyte antigen reveals a different pattern. New radiolabeled bands are much less intense than those observed with the lymphocyte antigen. Although several new bands are seen with proteolysis of both antigens, others appear to be unique to the lymphocyte antigen (particularly those having higher mol wt). No new bands unique to the granulocyte antigen are observed. Results are unchanged by treatment of isolated antigens with neuraminidase before proteolysis.

Despite the relative absence of discrete peptides from digests of the granulocyte antigen, successful proteolysis is confirmed by the reduced intensity of p110 bands in treated *v* control samples and a corresponding increase in counts present in low mol wt material at the gel front. All counts from the treated samples were transferred from the reaction vessels to the gel. Although comparable amounts of radioactive material were used in preparing all samples from the two cell types, some of those counts in the granulocyte samples reflect low mol wt species. Thus at least some of the differences in the bands between the two samples may be quantitative.

DISCUSSION

Our studies indicate that anti-CALLA MoAb identify antigens synthesized by both ALL cells and granulocytes

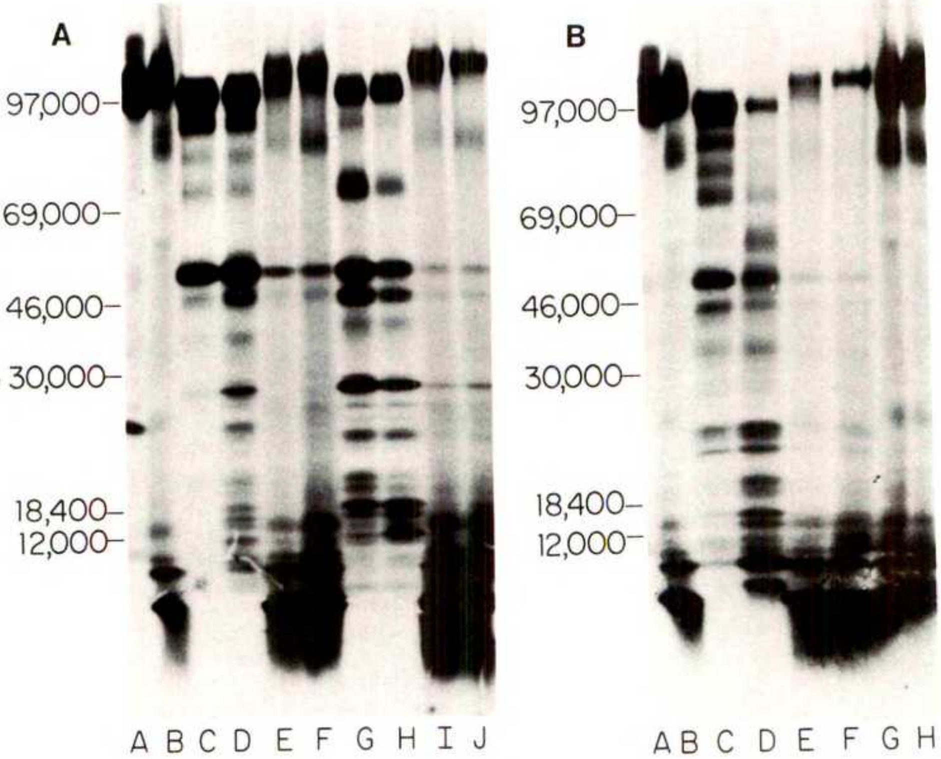

Fig 3. Proteolytic digests of iodinated antigens isolated from ALL cells (NALM-6) and human granulocytes by anti-CALLA-1 MoAb. Each antigen was treated with both 1 and 5 μg of each protease. Samples are as follows: Panel (A): A, sham-treated ALL antigen; B, sham-treated granulocyte antigen; C and D, ALL antigen treated with trypsin; E and F, granulocyte antigen treated with trypsin; G and H, ALL antigen treated with chymotrypsin; I and J, granulocyte antigen treated with chymotrypsin. Panel (B): A, sham-treated ALL antigen, B, sham-treated granulocyte antigen; C and D, ALL antigen treated with papain; E and F, granulocyte antigen treated with papain; G and H, sham-treated granulocyte antigen. Note the differences in mol wt between untreated antigens isolated from these two cell populations.

that have unique behavioral and chemical properties. Whereas the antigen on both normal and malignant lymphoid cells is readily modulated by specific antibody,[4-6] that on isolated granulocytes is not. The mol wt of the iodinated antigen on human granulocytes is higher than that on normal and malignant lymphoid cells and on the nonhematopoietic cells tested, indicating that previously observed differences were not due to individual variation.[9,10,12] In contrast, the mol wt of metabolically labeled antigen is lower in granulocytes than in lymphoid cells. Finally, proteolytic digests of the two antigens produce unique but overlapping banding patterns on SDS-PAGE.

Failure of the granulocyte antigen to modulate might reflect differences in either the integration of CALLA into the cell membrane of granulocytes and lymphocytes or the relative capacities of the surface structures of these two cell types to support antigenic modulation. Alternatively, the antigens detected on lymphoid cells and granulocytes may share an epitope(s) with one another but represent distinct chemical species. Because we have as yet no clear evidence that the five anti-CALLA MoAb used in our studies detect different antigenic determinants,[10] this latter possibility cannot be excluded.

Despite major differences in the antigens detected by anti-CALLA MoAb on ALL cells and granulocytes, it is still not known whether these antigens differ in their protein structures. The unique mol wt of these two antigens might well result from posttranslational modifications of a common peptide, such as the addition of carbohydrate residues.[17] Because differential glycosylation could modify both the sites of proteolysis and the mol wt of individual proteolytic fragments, the degree of homology of the peptide sequences of such antigens would be difficult to evaluate. Although analysis of the molecules from these two cell types in the total absence of glycosylation might clarify their relationship, production of such completely carbohydrate-free antigens is a difficult task. Amino terminal sequence analysis of the molecules on these two cell types might better address this issue.

AIDS Retrovirus Antibodies in Hemophiliacs Treated With Factor VIII or Factor IX Concentrates, Cryoprecipitate, or Fresh Frozen Plasma: Prevalence, Seroconversion Rate, and Clinical Correlations

By Margaret V. Ragni, Gary E. Tegtmeier, Jay A. Levy, Lawrence S. Kaminsky, Jessica H. Lewis, Joel A. Spero, Franklin A. Bontempo, Cindy Handwerk-Leber, William L. Bayer, Daniel H. Zimmerman, and Judith A. Britz

Antibodies to the AIDS retrovirus, specifically to human T cell lymphotropic virus, type III, and AIDS-associated retrovirus, were detected with increasing prevalence in a population of 190 hemophiliacs from western Pennsylvania between 1981 and 1984: 7.7% in 1981, 20.0% in 1982, 45.5% in 1983, and 62.5% in 1984. The seropositive included approximately three fourths of those receiving factor VIII concentrate, nearly one third of those receiving factor IX concentrate, nearly one fifth of those receiving cryoprecipitate, and none of those receiving fresh frozen plasma. The seroconversion rate, determined on 43 seropositive hemophiliacs from this group who were serially sampled, was 0% in 1977, 4.7% in 1978, 4.9% in 1979, 2.6% in 1980, 10.5% in 1981, 52.9% in 1982, 87.5% in 1983, and 100% in 1984. Of 27 seropositive for three or more years (since 1982 or before), four (15%) have developed AIDS and seven (26%), diffuse lymphadenopathy (ARC); of 16 seropositive for less than three years, none has developed AIDS and three (19%) have developed ARC. The mean time from seroconversion to onset of ARC, 0.8 ± 0.2 years (SEM), was shorter ($P < .001$) than the time to onset of AIDS, 4.1 ± 0.6 years. These findings confirm the widespread presence of AIDS retrovirus and support the association of these retroviruses with the acquired immunodeficiency syndrome and related conditions.

© 1986 by Grune & Stratton, Inc.

THREE GROUPS of investigators have isolated retroviruses from patients with the acquired immunodeficiency syndrome (AIDS) and AIDS-related syndromes. Termed lymphadenopathy-associated virus (LAV),[1] human T cell lymphotropic virus, type III (HTLV-III),[2] and AIDS-associated retrovirus (ARV),[3] these viruses appear to be nearly identical, with similar morphological, cytopathic, and molecular features.[1-5]

In hemophilia-related AIDS, transmission of the AIDS agent presumably occurs through exposure to blood products. Most hemophiliacs who have developed AIDS have been treated with factor VIII concentrate,[6] although the disease has been detected in several factor IX concentrate-treated hemophiliacs.[6] In addition, although AIDS has not yet occurred in hemophiliacs who have been treated with cryoprecipitate, two patients with von Willebrand's disease who were treated with cryoprecipitate have developed AIDS.[7] Correspondingly, AIDS retrovirus seropositivity has been detected primarily in those hemophiliacs receiving factor VIII concentrate,[8-12] to a lesser degree in those receiving factor IX concentrate, and in few, if any, receiving cryoprecipitate.[8-12]

This study evaluated the entire population of hemophiliacs from western Pennsylvania, exposed to factor VIII concentrate, factor IX concentrate, cryoprecipitate, or fresh frozen plasma, for the presence of antibodies to AIDS retroviruses, specifically antibodies to HTLV-III and ARV, between 1981 and 1984. This period coincided with the occurrence of AIDS in patients with hemophilia. Tests for antibodies to AIDS retrovirus isolates were used to determine whether any significant difference in antibody prevalence would be observed.

MATERIALS AND METHODS

Clinical population. Of the 190 hemophiliacs who constituted the entire hemophilic population in western Pennsylvania, 155 had hemophilia A and 35 had hemophilia B. Those with hemophilia A included 82 treated with factor VIII concentrate, 59 with cryoprecipitate, and 14 with factor IX concentrate because of the presence of an inhibitor to factor VIII. The last exposure to factor VIII concentrate in the latter group was before early 1976. Those with hemophilia B included 16 treated with factor IX concentrate and 19 with fresh frozen plasma. The mean age for those receiving factor VIII concentrate was 29.6 years, for factor IX concentrate 26.8 years, for cryoprecipitate 18.7 years, and for fresh frozen plasma 24.8 years.

Serum samples. Citrated plasma samples, obtained from all 190 hemophiliacs during routine clinical evaluation at the Hemophilia Center of Western Pennsylvania, were available for the assays described below. Only one blood sample per hemophiliac was tested in this study, specifically the first sample available beginning in 1984 and going back to 1981. In addition, 43 of the seropositive hemophiliacs on whom serial samples were available annually or biannually between 1977 and 1984 constituted the population base for determining the AIDS retrovirus seroconversion rate. This group, selected solely on the basis of their seropositivity and availability of serial samples, did not differ from the original 190 hemophiliacs in age, race, or blood product usage. Samples were frozen at −20 °C for several months to 6 years before the study.

Viral antibody tests. Antibodies (IgG) to HTLV-III were measured by an enzyme-linked immunosorbent assay (ELISA) technique (Electronucleonics, Inc, Columbia, Md), using an inactivated HTLV-III antigen from a previously established cell line.[11] Briefly, a 1:100 dilution of test plasma was added to a microassay-plate well that had been coated with inactivated virus antigen. After a 30-minute, 37 °C incubation, the unbound material was washed and aspirated. Goat antiserum to human IgG, both heavy and light chain

specific, labeled with horseradish peroxidase, was then added and incubated for 30 minutes at 37 °C. Unbound material was washed and aspirated, and a chromogen (*o*-phenylenediamine dichloride, or OPD) was added. After a 10-minute, room temperature incubation, the reaction was stopped with 2N sulfuric acid, and the absorbance was read spectrophotometrically at 492 nm. Samples giving an optical density >0.100 in two separate assays were considered positive.

For seroconversion data only, antibodies to HTLV-III (IgG) were detected by an ELISA technique (Abbott Laboratories, Chicago), using beads coated with inactivated HTLV-III antigen from the Hg/HTLV-IIIB cell line. A 1:400 dilution of test plasma was added to each bead-containing microassay-plate well and was incubated 65 minutes at 40 °C. Unbound material was washed and aspirated. Goat antihuman IgG, conjugated to horseradish peroxidase, was added and incubated for 130 minutes at 40 °C. Unbound material was washed and aspirated, and the chromogen (OPD) was added and incubated for 30 minutes at room temperature. The reaction was stopped with 1N sulfuric acid, and absorbance was read at 492 nm. Samples giving an optical density greater than or equal to a cutoff value, determined daily by negative and positive controls, were considered positive.

Antibodies to ARV were measured, as previously described,[3] by indirect immunofluorescence (IFA), using goat antiserum to human IgG, an adult human T cell line, HUT-78, infected with ARV-2, and a 1:10 dilution of test plasma. Four of the original 190 samples were of insufficient quantity for ARV antibody testing. Samples that were HTLV-III (Electronucleonics) seropositive, ARV seronegative or HTLV-III (Electronucleonics) seronegative, ARV seropositive were retested at a 1:5 dilution of test plasma, and the latter result was used in this study. There was no significant difference in the results obtained by ELISA with the HTLV-III antigen and those obtained by IFA with the ARV-2 antigen.

For the Western blot procedures (Electronucleonics), purified HTLV-III virus was reduced and electrophoretically resolved by polyacrylamide gel electrophoresis, using 12.5% running and 4% stacking gels at 150 V, pH 8.8. The resolved protein was transferred to nitrocellulose electrophoretically at 36 V for four hours, blocked with 20% goat serum in phosphate-buffered saline (PBS)/0.05% Tween (J.T. Baker Chemical Co, Phillipsburg, NJ), and cut into 0.5-cm strips. These strips were loaded with a 1:200 dilution of test plasma, incubated for two hours at room temperature, washed, and then incubated with a 1:2,000 dilution of goat antihuman IgG (heavy and light chain) conjugated to horseradish peroxidase. After serial washings, the substrate chloro-naphthol was added, and the strips were developed, blotted on bibulous paper, and dried. The test was considered positive if either the viral p24 or gp41 proteins were present.

Table 1. Prevalence of AIDS Retrovirus Antibodies in a Population of 190 Hemophiliacs

	AIDS Retrovirus Antibody	
	Number	Percentage
Prevalence by year sampled		
1981	2/26 (2/26)	7.7 (7.7)
1982	8/40 (6/40)	20.0 (15.0)
1983	20/44 (16/42)	45.5 (38.1)
1984	50/80 (54/78)	62.5 (69.2)
Total	80/190 (78/186)	42.1 (41.9)
Prevalence by blood product exposure		
F VIII	61/82 (60/81)	74.4 (74.1)
F IX	9/30 (10/30)	30.0 (33.3)
Cryo	10/59 (8/57)	17.0 (14.0)
FFP	0/19 (0/18)	0 (0.0)
Total	80/190 (78/186)	42.1 (41.9)

The data presented is the number (or percentage) seropositive over the total number tested for HTLV-III antibody, with similar data based on ARV antibody in parentheses. Only one blood sample per hemophiliac was used in this study—the first sample available from 1984 back to 1981. F VIII, factor VIII concentrate; F IX, factor IX concentrate; CRYO, cryoprecipitate; FFP, fresh frozen plasma.

Statistical analysis was performed by Student's *t* test.

RESULTS

The progressive yearly increase in AIDS retrovirus seropositivity in this group of hemophiliacs between 1981 and 1984 is shown in Table 1, with an overall prevalence for these years of 42.1% (80/190), respectively. The 80 seropositive included 74.4% of those receiving factor VIII concentrate, 30.0% of those receiving factor IX concentrate, 17.0% of those receiving cryoprecipitate, and 0% of those receiving fresh frozen plasma, respectively. The prevalence of seropositivity in factor IX concentrate-treated patients with hemophilia B was similar to that of factor IX concentrate-treated patients with hemophilia A and an inhibitor: of nine seropositive, five had hemophilia B and four had hemophilia A with an inhibitor.

Forty-three seropositive hemophiliacs from the group, on whom serially samples were available between 1977 and 1984, were further studied. None were seropositive in 1977 and two were seropositive in 1978. An increase in seroconversion rate occurred after 1980, with the most marked increase appearing in 1982 (Table 2). Seropositivity persisted in all individuals on repeat testing at later dates, and none reverted back to seronegative after becoming seropositive. When the date of first seroconversion was looked at in each blood product treatment group (Table 3), the first of 25 factor VIII concentrate-treated hemophiliacs seroconverted in 1978, the first of eight factor IX concentrate-treated hemophiliacs seroconverted in 1978, and the first of ten cryoprecipitate-treated hemophiliacs seroconverted in 1981. (The latter is a locally prepared single-donor product.) The eight factor IX concentrate-treated hemophiliacs included four factor IX-deficient individuals, three of whom seroconverted in 1983

Table 2. AIDS Retrovirus Seroconversion Rate

Year	No. Becoming Seropositive/ No. Remaining Seronegative	Percentage
1977	0/43	0.0
1978	2/43	4.7
1979	2/41	4.9
1980	1/39	2.6
1981	4/38	10.5
1982	18/34	52.9
1983	14/16	87.5
1984	2/2	100.0

The determination of seroconversion rate was based on serial samples on 43 AIDS retrovirus seropositive hemophiliacs between 1977 and 1984. Seroconversion rate was expressed as a percentage and defined for each year as the number becoming seropositive (seroconverting) in a given year over the number remaining seronegative that year.

*F VIII refers to hemophiliacs treated with factor VIII concentrate, F IX refers to those treated with factor IX concentrate, and cryo refers to those treated with cryoprecipitate.

†Patient developed AIDS.

‡Patient developed diffuse lymphadenopathy (ARC).

and the fourth of whom seroconverted in 1984; the other four factor IX concentrate-treated hemophiliacs included four factor VIII-deficient individuals with an inhibitor to factor VIII whose last exposure to factor VIII was before early 1976, one of whom seroconverted in 1978, one in 1982, and two in 1983.

From this group of 43 sequentially sampled hemophiliacs, four (9%) developed AIDS and ten (23%) developed diffuse lymphadenopathy (ARC). Of the 27 who have been seropositive for three or more years (1982 or earlier seroconversion), four (15%) have developed AIDS and seven (20%) have developed diffuse lymphadenopathy (Table 3). In addition, one (4%) developed immune thrombocytopenia (also had AIDS). Of the 16 who have been seropositive for less than three years (1983 or later seroconversion), none has developed AIDS and three (19%) have developed ARC. The mean time from seroconversion to onset of ARC in all ten with ARC was 0.8 ± 0.2 years (SEM) (range, 0 to 2) which was significantly shorter ($P < .001$) than the time to onset of AIDS in all four with AIDS, 4.0 ± 0.6 years (range, 3 to 6).

The total yearly blood product usage (units per year) in patient sampled in 1984 (Table 4) revealed that a significantly greater amount of factor VIII concentrate was used in seropositive hemophiliacs than in seronegative hemophiliacs. The factor IX concentrate usage appeared to be twice as high in seropositive hemophiliacs as in seronegative hemophiliacs, but this difference was not significant. There appeared to be no difference in cryoprecipitate usage between seropositive and seronegative hemophiliacs. Because of small numbers and incomplete data, comparisons could not be made for 1981 through 1983, except for factor VIII concentrate usage in 1983, which was significantly greater ($P < .005$) (data not shown) in seropositive hemophiliacs compared with seronegative hemophiliacs.

DISCUSSION

The increasing prevalence of antibodies to AIDS retrovirus in this group of hemophiliacs between 1981 and 1984 parallels the occurrence of AIDS in the hemophiliac population.[6] Further, the strong correlation between the presence of antibodies to HTLV-III and ARV in these patients measured by different assays is consistent with data showing that HTLV-III and ARV (as well as LAV) are variants of the same virus.[4,5] The fact that all hemophiliacs with AIDS or AIDS-related illness in this study were AIDS retrovirus (both HTLV-III and ARV) seropositive supports the close association of these retroviruses with AIDS and AIDS-related conditions. Detection of AIDS retrovirus antibodies (HTLV-III or ARV) in the majority of western Pennsylva-

Table 4. Blood Product Usage and AIDS Retrovirus Antibody Status in 1984

Blood Product	Antibody (+)	Antibody (−)	*P*
F VIII concentrate	66,637 ± 13,086 (n = 41)	18,603 ± 7,354 (n = 6)	<.005
F IX concentrate	58,053 ± 12,951 (n = 4)	27,310 ± 7,101 (n = 5)	NS
Cryoprecipitate	19,000 ± 6,223 (n = 3)	19,925 ± 5,476 (n = 8)	NS
Fresh frozen plasma	— (n = 0)	7,585 ± 4,819 (n = 2)	—

Data are based on blood product usage between September 1983 and August 1984. Figures in parentheses are the number on whom data were available. Data presented are based on HTLV-III antibody positive and negative hemophiliacs; corresponding data for ARV antibody positive and negative were not significantly different. Results are expressed as the mean ± standard error (SEM).

nia hemophiliacs, similar to data reported in San Francisco homosexuals[3] and hemophiliacs[12] and in Australian bisexual and homosexual males,[13] demonstrates that exposure to the AIDS retrovirus is widespread geographically. Moreover, the AIDS virus appears to have been present here at least since 1978, one year earlier than that found in a smaller study[14] by Eyster et al, but still consistent with the occurrence of the earliest cases of AIDS in the United States in 1978 and 1979.

The predominance of AIDS retrovirus seropositivity in factor VIII concentrate-treated hemophiliacs parallels the higher incidence of AIDS in hemophiliacs treated with this blood product. The markedly lower prevalence of antibodies in hemophiliacs exposed to factor IX concentrate is consistent with the infrequent occurrence of AIDS in this group.[6] The presence of such antibodies in cryoprecipitate-treated hemophiliacs, a group in which AIDS has not yet occurred, further supports the recommendation of the use of heat-treated factor VIII concentrate to prevent transmission of potentially infectious retroviruses.[15,16]

The marked increase in seroconversion that occurred in 1982 is in agreement with a similar study of hemophiliacs treated only with factor VIII concentrate.[14] The time of occurrence and the percentage of virus-exposed individuals developing disease are a noteworthy observation. They offer some indication of the risk of pathogenic consequences after exposure to the virus in hemophiliacs and mirror similar observations with other AIDS risk groups.[17] Further, these data suggest that a large number of hemophiliacs were exposed through their clotting factor treatment to infectious viruses and not just viral antigens. The short time between the date of seroconversion and the development of diffuse adenopathy in ten hemophiliacs supports the view that this clinical sign can be an early manifestation of AIDS retrovirus infection or exposure. The reason for the longer time between seroconversion and development of AIDS in four hemophiliacs is not clear but probably reflects the indolent disease course that eventually leads to widespread compromise of the immune system by AIDS retrovirus infection.

In Situ Quantitation of Lymph Node Helper, Suppressor, and Cytotoxic T Cell Subsets in AIDS

By Gary S. Wood, Bruce F. Burns, Ronald F. Dorfman, and Roger A. Warnke

We have used the novel monoclonal antibodies 9.3 and anti-Leu-8 in conjunction with other T cell markers to quantify T cell subpopulations in the paracortex, mantle, and germinal center compartments of frozen sections of lymph nodes from seven homosexual men with acquired immunodeficiency syndrome (AIDS) and five heterosexual controls. Antibody 9.3 allows dissection of the Leu-2$^+$ cytotoxic/suppressor subset (T_{cs}) into 9.3$^+$ cytotoxic cells (T_c) and 9.3$^-$ suppressor cells (T_s). Anti-Leu-8 allows dissection of the Leu-3$^+$ helper subset (T_H) into functionally distinct subpopulations. The data indicate that the T cells in patients with AIDS exhibit normal antigen expression but altered subset ratios. In this series, the data suggested that the reversal of the paracortical T_H-T_{cs} ratio was due to an increase in T_s with a concomitant decrease in T_H and T_c. These changes were also reflected in a reversal of the normal paracortical T_c-T_s ratio (3.0) to <1.0. Furthermore, the data suggested a marked decrease in paracortical Leu-3$^+$8$^+$$T_H$, which are known to have inducer function in cellular immune reactions and exert feedback inhibition of immunoglobulin production through a suppressor T cell intermediary. In contrast, there was preservation of the Leu-3$^+$8$^-$$T_H$ population within the germinal center. This T cell subset is known to help B cell differentiation. This microenvironmentally specific constellation of T cell subset alterations within lymph nodes may in part explain several of the immunologic findings associated with AIDS.

© 1986 by Grune & Stratton, Inc.

DURING THE PAST FEW YEARS, several studies have documented quantitative and qualitative abnormalities of peripheral blood T cells obtained from homosexual men with acquired immunodeficiency syndrome (AIDS).[1-13] These abnormalities include decreased total circulating T cells, a decreased helper-cytotoxic/suppressor ratio, reduced response to mitogens, and diminished in vitro helper activity. Similar peripheral blood abnormalities have been identified in patients from other groups at risk for AIDS.[4,8-11,14-20] Related immunohistologic studies of T cells within lymph nodes have documented changes within the paracortical T cell domain that parallel those noted previously in the blood.[9,21-23]

These immunophenotypic studies of blood and lymphoid tissue have generally used a relatively small panel of monoclonal antibodies, including anti-Leu-3(T4) and anti-Leu-2(T8). Consequently, it has been difficult to determine whether T cell populations in AIDS exhibit normal or abnormal patterns of antigen expression, as often occurs in T cell neoplasia.[24-26] Furthermore, although commonly referred to as the helper-suppressor ratio, the Leu-3(T4)-Leu-2(T8) ratio is actually a comparison of two heterogeneous T cell subsets.[27,28] The availability of two additional monoclonal antibodies, anti-Leu-8[27] and 9.3,[28] has made it possible to further dissect these subsets. The Leu-3(T4)$^+$ subset contains Leu-8$^-$ helper T cells (T_H) that help B cell differentiation and Leu-8$^+$ T_H primarily concerned with other types of inducer function.[27] The Leu-2(T8)$^+$ subset contains 9.3$^+$ cytotoxic T cells (T_c) as well as 9.3$^-$ suppressor T cells (T_S).[28]

Recent studies of peripheral blood T cells in homosexual men with the syndrome of persistent generalized lymphadenopathy (PGL) have documented decreased T4$^+$Leu-8$^+$ cells and increased T8$^+$Leu-8$^-$ cells.[18] In the present study, we have used immunoperoxidase techniques and a large panel of anti-T cell monoclonal antibodies, including anti-Leu-8 and 9.3, to characterize and quantitate T cell subsets in situ in lymph nodes from homosexual men with AIDS and heterosexual controls.

MATERIALS AND METHODS

Patients and controls. Lymph node biopsies were obtained from seven homosexual men with AIDS and five heterosexual controls. The selection of patients was based on the availability of frozen tissue for immunohistologic studies. The average patient age was 32 years (range, 25 to 49). One patient died of cytomegalovirus/*Pneumocystis carinii* pneumonia (CMV/PCP). The remaining six patients were alive with cutaneous or nodal Kaposi's sarcoma. Generalized lymphadenopathy was present in all patients except one with Kaposi's sarcoma. The selection of heterosexual controls was determined by diagnosis of nonspecific reactive follicular hyperplasia in lymph nodes, the lack of generalized lymphadenopathy, and the availability of frozen tissue. The average control age was 30 years (range, 17 to 41).

Lymph nodes from patients with Kaposi's sarcoma demonstrated reactive follicular hyperplasia, sometimes with partial effacement of follicular mantle zones. In those lymph nodes that were partially involved by Kaposi's sarcoma, there was less prominent follicular hyperplasia. Regressively transformed germinal centers were also observed. Lymph nodes from the patient with CMV/PCP exhibited a lymphocyte depletion pattern manifested by decreased paracortical lymphocytes, fibrosis, and absent B cell follicles. The histopathology of some of these lymph node biopsies has been detailed elsewhere.[29]

Immunohistology. All lymph nodes were obtained at surgical biopsy except for those from the patient with CMV/PCP. The latter were obtained at autopsy within a few hours of death. Representative portions were cryopreserved, sectioned, and stained with a three-stage monoclonal antibody-biotin-avidin immunoperoxidase technique, as described previously.[30] The panel of monoclonal antibodies that was used is listed in Table 1, along with predominant specificities and sources.

Blood, Vol 67, No 3 (March), 1986: pp 596-603

Table 1. Monoclonal Antibodies

Antibody (Antigen)	Predominant Specificity
Anti–Leu-1 (CD5)	T cells, thymocytes
Anti–Leu-2 (CD8)	Cytotoxic/suppressor T cells, thymocytes
Anti–Leu-3 (CD4)	Helper T cells, thymocytes, histiocytes
Anti–Leu-4 (CD3)	T cells, thymocytes
Anti–Leu-5 (CD2)	T cells, thymocytes
Anti–Leu-6 (CD1)	Thymocytes, Langerhans cells
Anti–Leu-8	Blood: 75% ± 10% Leu-3$^+$ T cells; 60% ± 10% Leu-2$^+$ T cells; majority of B cells, NK cells, monocytes, and granulocytes
9.3	Blood: Helper T cells, cytotoxic T cells
OKT9 (T9, transferrin receptor)	Thymocytes, several other actively proliferating cell types, including germinal center cells
OKT10 (T10)	Thymocytes, plasma cells
L203 (HLA-DR)	B cells, histiocytes, activated T cells

Antibodies were obtained from the following sources: Anti–Leu-1, -2, -3, -4, -5, -6, and -8 from Becton Dickinson, Mountain View, Calif., 9.3 from John Hansen, Seattle, courtesy of Edgar Engleman, Stanford University; OKT9 and OKT10 from Ortho Pharmaceuticals, Raritan, NJ; L203 from Ronald Levy, Stanford University.

The peripheral blood reactivity of anti–Leu-8 and 9.3 is detailed elsewhere[27,28] but will be reviewed here briefly (Table 2). Anti–Leu-8 stains 75% ± 10% of Leu-3$^+$ cells, 60% ± 10% of Leu-2$^+$ cells, and the majority of B cells, natural killer cells, monocytes, and granulocytes. Its reactivity has been reported to be similar to that of another monoclonal antibody, anti-TQ1,[18] although these two antibodies do not cross-block.[27] Antibody 9.3 stains virtually all Leu-3$^+$ cells and approximately 50% of Leu-2$^+$ cells in peripheral blood. Leu-2$^+$ 9.3$^+$ T cells have cytotoxic function, whereas Leu-2$^+$ 9.3$^-$ T cells have suppressor function.[28] Within the peripheral blood, 9.3 staining appears to be restricted to T cells.[28]

Table 2. Dissection of T Cell Phenotypes With Monoclonal Antibodies

	T Cell Phenotype		
Antibody	T_H	T_C	T_S
Leu-2	−	+	+
Leu-3	+	−	−
Leu-4	+	+	+
9.3	+	+	−
9.3 − Leu-3	−	+	−
Leu − 4-9.3	−	−	+
Leu-8	+/−	+/−	+/−

In Situ *quantitation of T cell subsets.* T cell subsets were quantitated within the major T and B cell compartments of the lymph node: the paracortex (T cell domain), the mantle zone (B cell domain), and the germinal center (B cell domain) (Table 3). Semiserial sections were scanned at lower power to select two areas representative of each compartment. All cell counts were obtained from these same two areas. A square, cross-hatched grid mounted in an American Optical (Buffalo) 15× microscope eyepiece was then used to count cells under the 40× objective. At this magnification, the grid measured 0.25 mm on each side. The cells within the grid area that stained with anti–Leu-2, -3, -4, -8, or 9.3 were counted. The two values generated for each antibody were then averaged to give the mean value for the compartment as a whole. Histiocytes, which were variably Leu-3$^+$,[31] were excluded from Leu-3$^+$ T cell counts.

Based on the phenotypic and functional data reviewed above and in Tables 1 and 2, T cell subsets were defined as follows: T cells (Leu-4$^+$), helper T cells (T_H) (Leu-3$^+$), cytotoxic/suppressor T cells (T_{cs}) (Leu-2$^+$), cytotoxic T cells (T_c) (9.3$^+$ minus Leu-3$^+$), and suppressor T cells (T_s) (Leu-4$^+$ minus 9.3$^+$). Various T cell subset ratios were then calculated based on these values. The data in Table 3 represent the means for each T cell subset or ratio calculated from the seven homosexual men with AIDS and the five controls. Quantitation of paracortical T cell subsets as percentages of the combined

The values shown are the means of the absolute number of cells per grid area, with the range in parentheses.

*$P \leq .01$ relative to controls; $P > .05$ for all other values.

Table 4. Quantitation of Paracortical Leu-8⁺ Cells and Non-T Cells in AIDS v Controls

	Leu-8⁺ Cells	T015⁺ (B) Cells	Leu-M3⁺/ 63D3⁺ Cells (Histiocytes)	Leu-7⁺ (NK) Cells
Controls	866	61	14	3
(n = 5)	(814-934)	(22-110)	(5-20)	(0-6)
AIDS	262*	97	42*	9*
(n = 7)	(70-644)	(62-156)	(18-79)	(5-14)

The values shown are the means of the absolute number of cells per grid area, with the range in parentheses.

*$P \leq .01$ relative to controls.

paracortical T cell, B cell, histiocyte, and NK (natural killer/killer) cell population also required quantitation of the absolute number of paracortical T015⁺ B cells,[32] Leu-M3⁺ or 63D3⁺ histiocytes,[33,34] Leu-7⁺ NK cells,[35] and Leu-8⁺ cells (Table 4). These additional data concerning non-T cell subsets are presented in detail elsewhere.[36] Statistical significance was assessed with the two-tailed Wilcoxon two-sample rank test (Mann-Whitney test).

The internal consistency of the quantitation technique was assessed by comparing the sum of Leu-2⁺ and Leu-3⁺ cells v Leu-4⁺ cells in all three tissue compartments in both patients and controls. As shown in Table 5, there was good correlation between these two values in each instance. Furthermore, the number of T_c (9.3⁺ minus Leu-3⁺) was always less than the number of T_{cs} (Leu-2⁺). Similarly, T_s (Leu-4⁺ minus 9.3⁺) was always less than T_{cs} (Leu-2⁺).

Estimation of Leu-3⁺8⁺ paracortical cells. A minimum/maximum analysis was performed in order to estimate the difference in the number of Leu-3⁺8⁺ paracortical cells in patients v controls (Table 5). The maximum possible absolute number of Leu-3⁺8⁺ cells was either the Leu-3⁺ cell total or the Leu-8⁺ cell total—whichever was less. The minimum possible absolute number of Leu-3⁺8⁺ cells was either 0 or the total absolute number of cells in all other subsets (T_{cs}, B cell, histiocyte, and NK) subtracted from the Leu-8⁺ cell total—whichever was greater. The absolute numbers of cells in each subset from each patient and control were used for these calculations (Tables 3 and 4). The absolute numbers of Leu-3⁺8⁺ cells were also expressed as percentages relative to total Leu-3⁺ cells.

RESULTS

Controls. The paracortical T_H-T_{cs} (Leu-3⁺-Leu-2⁺) ratio averaged 4.06 in controls (Table 3). Further dissection of the Leu-2⁺ T_{cs} subset with antibody 9.3 indicated that cells of T_c phenotype were the predominant Leu-2⁺ subpopulation with a T_c-T_s ratio averaging 2.96. As such, the calculated T_H-T_s ratio averaged 16.85. This was considerably higher than the Leu-3⁺-Leu-2⁺ ratio (4.06), which, although often referred to as the helper-suppressor T cell ratio, actually represents the helper-cytotoxic/suppressor T cell ratio. The mean absolute values for control paracortical T_H, T_c, and T_s (Table 3) are shown in Fig 1.

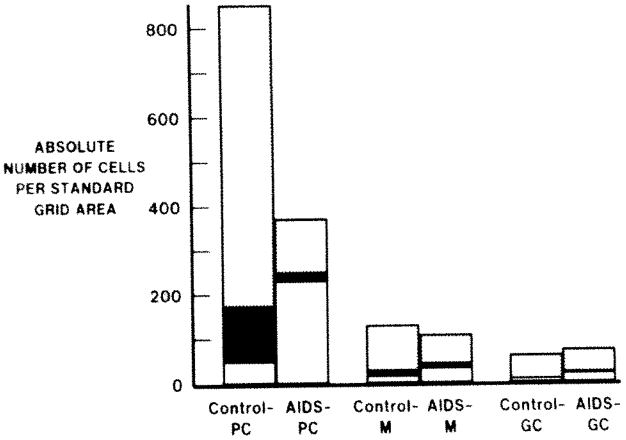

Fig 1. Alterations of T cell subsets in AIDS v controls. The histogram is based on the mean values for T_H (gray), T_c (black), and T_s (white) as detailed in Table 3. Within the paracortex (PC) in AIDS, there was a marked reduction in total T cells, T_H, and T_c, while T_s were increased ($P \leq .01$). No statistically significant quantitative alterations were noted within the mantle (M); however, within the germinal center (GC), T_s were increased ($P \leq .01$).

Quantitation of 9.3⁺ cells and comparison to Leu-4⁺ cells revealed that 9.3 stained slightly fewer cells than anti–Leu-4 within the paracortex (mean, 95%), mantle (mean, 92%), and germinal center (mean, 94%). Both antibodies had a similar distribution pattern, suggesting that 9.3 is restricted to cells of T lineage. In contrast, anti–Leu-8 stained the vast majority of cells within both the paracortex and the mantle, which contain a predominance of T cells and B cells, respectively. Furthermore, Leu-8⁺ cells were virtually absent within the germinal center. Representative immunohistologic staining of control lymph nodes is shown in Fig 2.

Leu-8⁺ cells, B cells, histiocytes, and NK cells were quantitated within the paracortex (Table 4). The immunohistology of the non-T cells is presented in detail elsewhere.[36] In conjunction with the paracortical values listed in Table 3, these data allowed calculation of the percentages of various T cell subsets relative to the total number of paracortical T cells, B cells, histiocytes, and NK cells (Fig 3). These data indicated that within the paracortex, the majority of total T cells, T_H, T_{cs}, and T_c were Leu-8⁺, since Leu-8⁻ cells constituted only 6% of the paracortical combined T cell, B cell, histiocyte, and NK cell population, whereas these T cell groups constituted 92%, 74%, 20%, and 14%, respectively. In

Table 5. Internal Consistency of Quantitation Technique: Leu-2⁺ + Leu-3⁺ v Leu-4⁺

	Paracortex (Controls, n = 5; AIDS, n = 7)		Mantle (Controls, n = 5; AIDS, n = 5)		Germinal Center (Controls, n = 5; AIDS, n = 6)	
	Leu-2⁺ + Leu-3⁺	Leu-4⁺	Leu-2⁺ + Leu-3⁺	Leu-4⁺	Leu-2⁺ + Leu-3⁺	Leu-4⁺
Controls	864	849	154	148	59	58

	(176-615)	(174-628)	(62-142)	(50-140)	(55-94)	(51-94)

The values shown are the means of the absolute number of cells per grid area, with the range in parentheses.

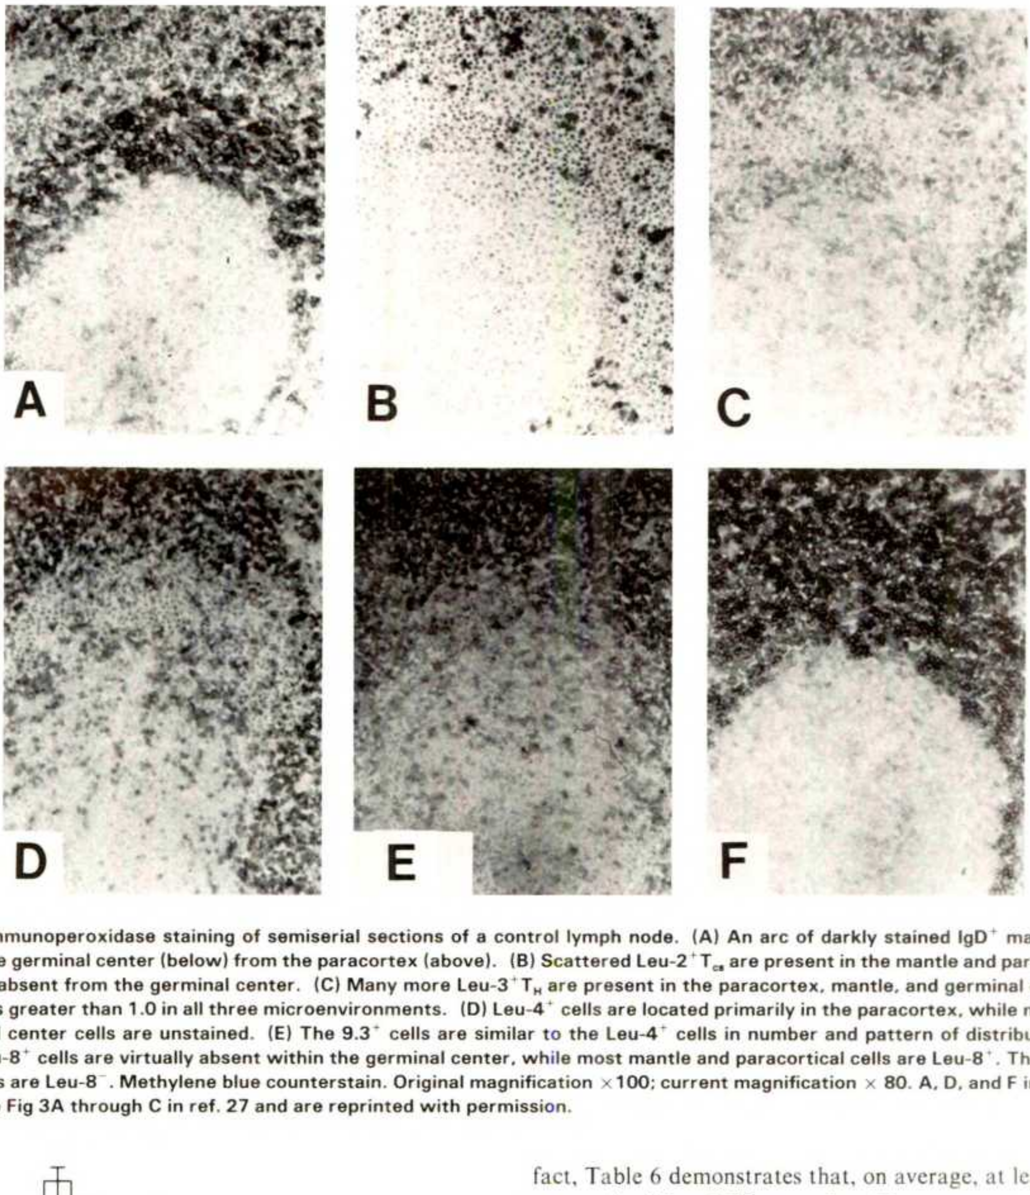

Fig 2. Immunoperoxidase staining of semiserial sections of a control lymph node. (A) An arc of darkly stained IgD^+ mantle B cells separates the germinal center (below) from the paracortex (above). (B) Scattered Leu-2^+ T_{cs} are present in the mantle and paracortex but are virtually absent from the germinal center. (C) Many more Leu-3^+ T_H are present in the paracortex, mantle, and germinal center. The T_H-T_{cs} ratio is greater than 1.0 in all three microenvironments. (D) Leu-4^+ cells are located primarily in the paracortex, while most mantle and germinal center cells are unstained. (E) The 9.3^+ cells are similar to the Leu-4^+ cells in number and pattern of distribution. (F) In contrast, Leu-8^+ cells are virtually absent within the germinal center, while most mantle and paracortical cells are Leu-8^+. Thus germinal center T cells are Leu-8^-. Methylene blue counterstain. Original magnification ×100; current magnification × 80. A, D, and F in this figure are similar to Fig 3A through C in ref. 27 and are reprinted with permission.

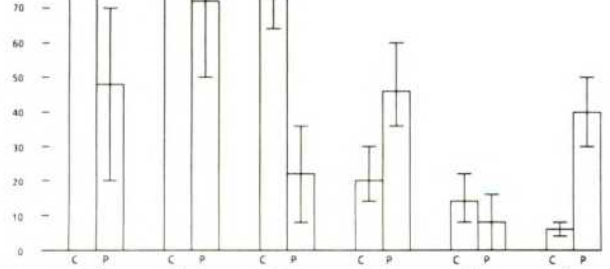

Fig 3. Paracortical Leu-8^+ and T cell subsets: relative alterations in AIDS *v* controls. Calculations are based on the absolute numbers of paracortical T, T_H, T_{cs}, T_c, T_s, Leu-8^+ cells, B cells, histiocytes, and NK cells as listed in Tables 3 and 4. Percentages are expressed relative to total T cells, B cells, histiocytes, and NK cells. Each bar represents the mean value with the range indicated by the T bar extensions. $P \leq .01$ relative to controls for each subset diagrammed except T_c. C, controls; P, patients.

fact, Table 6 demonstrates that, on average, at least 90% of paracortical Leu-3^+ T_H were Leu-8^+.

In addition to Leu-4, T cells within all three compartments also stained for other mature T cell antigens (Leu-1 and Leu-5), lacked immature T cell antigens (Leu-6, OKT9, OKT10), and were generally HLA-DR^-.

Homosexual men with AIDS. When compared with the control group (Tables 3 and 4), the homosexual men with AIDS exhibited several statistically significant differences ($P < .01$): (1) total T cells, T_H, and T_c were decreased in the paracortex; (2) T_s were increased in the paracortex and germinal center; (3) although the T_H-T_s ratio was decreased in all three compartments, only the paracortex showed a reversal of this ratio of <1.0; (4) the T_c-T_s ratio was reversed to <1.0 in the paracortex: (5) Leu-8^+ cells were decreased in the paracortex; (6) histiocytes and NK cells were increased in the paracortex. Virtually all germinal center cells were Leu-8^-, and there was no significant change in the number of Leu-3^+ T_H in this compartment. Alterations in the mean absolute number of T_H, T_c, and T_s are shown in Fig 1.

Table 6. Quantitation of Paracortical Leu-3^+8^+ Cells

				Leu-3^+8^+: Minimum* and Maximum† Limits	
	Leu-3^+	Leu-8^+	Leu-2^+, Leu-7^+, Leu-M3^+, and T015^+	Absolute Number	Percentage Relative to Leu-3^+ Cells
Controls	678	866	264	603 – 678	90 – 100
(n = 5)	(550–756)	(814–934)	(178–365)	(533–697) (550–756)	(81–99) (100)
AIDS	124‡	262‡	390	5‡ – 124‡	2‡ – 100
(n = 7)	(26–243)	(70–466)	(266–552)	(0–36) (26–243)	(0–15) (100)

The values shown are the means of the absolute number of cells per grid area (except where labeled as percentages) with the range in parentheses.

*Zero or [Leu-8^+-(Leu-2^+, Leu-7^+, Leu-M3^+, and T015^+)], whichever was greater. See Materials and Methods for further details.

†Leu-3^+ or Leu-8^+, whichever was less. See Materials and Methods for further details.

‡$P \leq .01$ relative to controls.

Representative immunohistologic staining of AIDS lymph nodes is shown in Figs 4 and 5.

The marked decrease in Leu-8^+ paracortical cells from 94% in controls to 48% in AIDS patients (Fig 3) was further explored for the Leu-3^+ T cell subset. Table 6 demonstrates that the absolute number of paracortical Leu-3^+8^+ T_H was severely reduced in AIDS *v* controls. Although these data did not reveal the exact size of the reduction, they did allow calculation of the limits of this decrease. The maximum possible decrease was the control maximum (678) minus the AIDS minimum (5), which equals 673, or 99% of the control maximum. The minimum possible decrease was the control minimum (603) minus the AIDS maximum (124), which equals 479, or 79% of the control minimum. Thus the actual reduction of Leu-3^+8^+ T_H in AIDS fell somewhere between the limits of 479 and 673 cells per grid area, which represents a decrease of at least 79%. Because a similar analysis of the paracortical Leu-3^+8^- subset was consistent with either an increase or a decrease in AIDS *v* controls, it was not possible to determine how this subset was quantitatively altered in the paracortex in AIDS. However, because germinal centers were essentially devoid of Leu-8^+ cells, it was apparent that the increased T_s and the unchanged T_H within the germinal center belonged to the Leu-8^- subset.

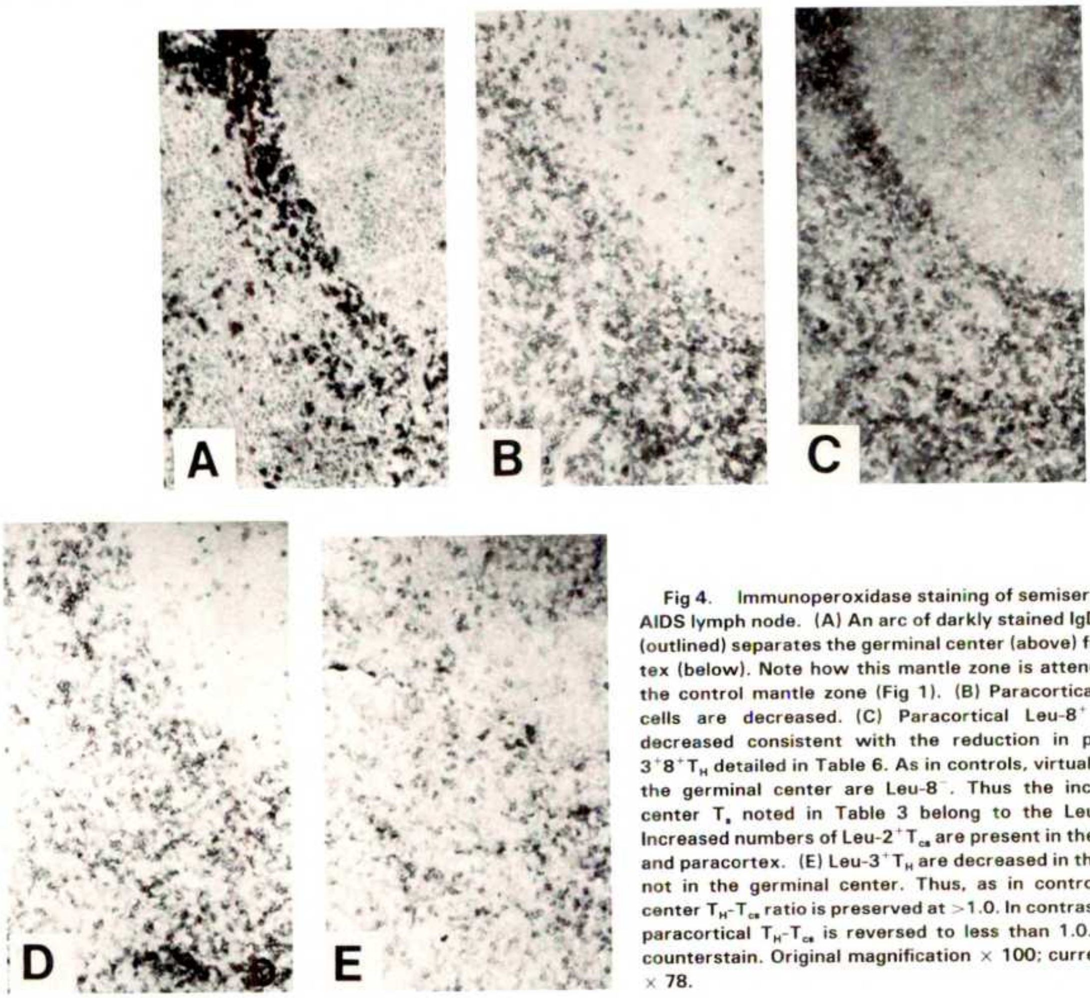

Fig 4. Immunoperoxidase staining of semiserial sections of an AIDS lymph node. (A) An arc of darkly stained IgD$^+$ mantle B cells (outlined) separates the germinal center (above) from the paracortex (below). Note how this mantle zone is attenuated relative to the control mantle zone (Fig 1). (B) Paracortical Leu-4^+ total T cells are decreased. (C) Paracortical Leu-8^+ cells are also decreased consistent with the reduction in paracortical Leu-3^+8^+ T_H detailed in Table 6. As in controls, virtually all cells within the germinal center are Leu-8^-. Thus the increased germinal center T_s noted in Table 3 belong to the Leu-8^- subset. (D) Increased numbers of Leu-2^+ T_{cs} are present in the germinal center and paracortex. (E) Leu-3^+ T_H are decreased in the paracortex but not in the germinal center. Thus, as in controls, the germinal center T_H-T_{cs} ratio is preserved at >1.0. In contrast to controls, the paracortical T_H-T_{cs} is reversed to less than 1.0. Methylene blue counterstain. Original magnification × 100; current magnification × 78.

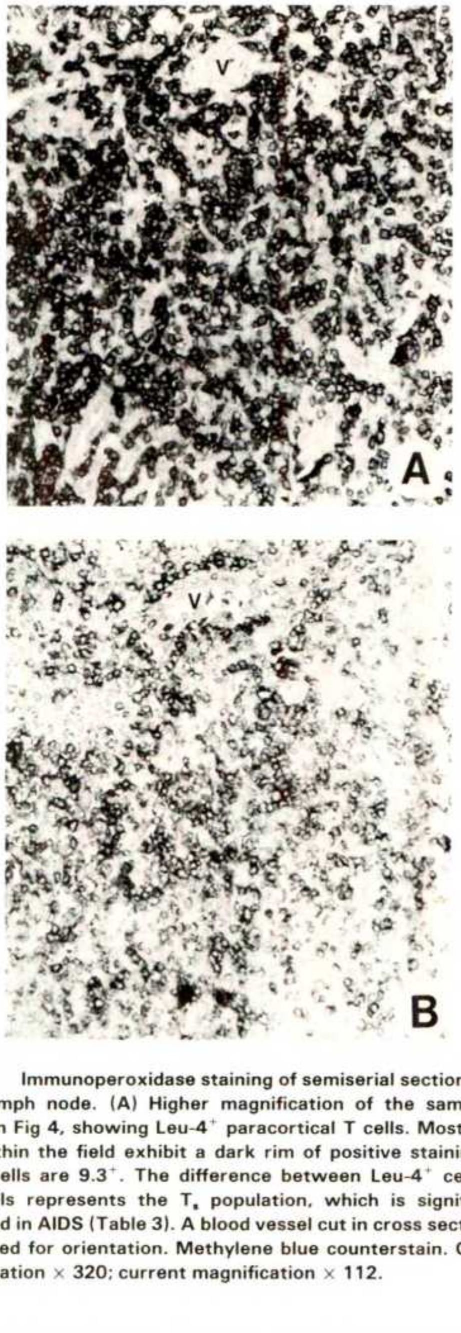

Fig 5. Immunoperoxidase staining of semiserial sections of an AIDS lymph node. (A) Higher magnification of the same case shown in Fig 4, showing Leu-4$^+$ paracortical T cells. Most of the cells within the field exhibit a dark rim of positive staining. (B) Fewer cells are 9.3$^+$. The difference between Leu-4$^+$ cells and 9.3$^+$ cells represents the T_s population, which is significantly increased in AIDS (Table 3). A blood vessel cut in cross section (V) is included for orientation. Methylene blue counterstain. Original magnification × 320; current magnification × 112.

As in the control group, T cells exhibited normal patterns of antigen expression in regard to the presence of Leu-1 and Leu-5 and the absence of Leu-6, OKT9, and OKT10. The majority of T cells were HLA-DR$^-$.

DISCUSSION

The most widely reported phenotypic abnormality in patients with AIDS, inversion of the Leu-3$^+$-Leu-2$^+$ ratio,[1-16] is a nonspecific finding that has been documented in a wide variety of clinical settings.[8-11,17-20,22,37-43] Interpretation of the Leu-3$^+$-Leu-2$^+$ ratio is complicated by the fact that anti–Leu-3(T4) antibodies react variably with monocytes, macrophages, and dendritic cells[31] and may thereby artifactually increase the ratio. In the present study, we omitted Leu-3$^+$ histiocytes from our counts of Leu-3$^+$ T cells and verified this by noting that the difference between Leu-4$^+$ and Leu-2$^+$ cell counts approximated the Leu-3$^+$ cell count (Table 5).

Another difficulty involving the Leu-3$^+$-Leu-2$^+$ ratio is that, although often referred to as the helper-suppressor ratio, it is actually the helper-cytotoxic/suppressor ratio, since anti–Leu-2(T8) stains T_c as well as T_s subsets.[28] The use of antibody 9.3 (which stains T_H and T_c but not T_s) in conjunction with other T cell markers allows dissection of T cells into separate T_H, T_c, and T_s phenotypes (Table 2). Using this principle, we documented marked differences between T_H-T_s and T_H-T_{cs} ratios (Table 3). These were more apparent in the paracortex of control lymph nodes than in AIDS lymph nodes, since in the latter most Leu-2$^+$ T cells were T_s, whereas in the former most Leu-2$^+$ cells were T_c.

Beyond assessment of the Leu-3$^+$-Leu-2$^+$ ratio, our quantitative immunohistologic analysis of lymph nodes from AIDS patients revealed that most of the alterations among T cell subsets were restricted to the paracortical T cell domain. In contrast, except for an increase in Leu-8$^-$ T_s, the germinal center B cell domain had a normal complement of T cells and a T_H-T_s ratio >1.0 (Table 7).

Because the quantitation of certain T cell subsets, including T_c, T_s, and those in Table 6, require indirect calculations, they are more prone to error than are direct measurements and should be regarded as approximations rather than as definitive values. Furthermore, knowledge of the full functional repertoire of the T cell subsets defined by 9.3 and anti–Leu-8 is still evolving. Nevertheless, it is possible to suggest certain correlations among T cell phenotypes and functions in AIDS in the context of our current quantitative data.

Our studies demonstrated that Leu-3$^+$8$^-$ T_H are intact within the germinal center B cell domain in AIDS. This subset is known to provide the major helper effect for B cell differentiation into immunoglobulin-secreting cells.[27] In addition, both Leu-2$^+$8$^+$ and Leu-2$^+$8$^-$ T cells are required to suppress this helper function.[27] While Leu-2$^+$ T_s are increased within the germinal center in AIDS, they are virtually all Leu-8$^-$. Thus they may not be optimal suppressors of certain B cell activities. In addition, the germinal center T_H-T_s ratio is relatively preserved at >1.0. Although we were unable to quantitate paracortical Leu-3$^+$8$^-$ T_H, the normal levels of this subset within germinal centers, together

Table 7. Microenvironmentally Specific Alterations of T Cell Subsets in AIDS

	Lymph Node Microenvironment	
Parameter	Germinal Center (B Cell)	Paracortex (T Cell)
No. of Leu-3$^+$8$^-$ (helper) T cells	Normal	Undetermined
No. of Leu-3$^+$8$^+$ (helper) T cells	Normal	Decreased
No. of 9.3$^+$, Leu-2$^+$ (cytotoxic) T cells	Normal	Decreased
No. of 9.3$^-$, Leu-2$^+$ (suppressor) T cells	Increased	Increased
T_H-T_{cs} and T_H-T_s ratios	>1.0	<1.0

From our data, it was not possible to determine whether Leu-3$^+$8$^-$ T cells were increased or decreased within the paracortex.

with the previously reported normal levels of peripheral blood Leu-$3^+8^-T_H$ in homosexual men with PGL,[18] suggest that normal levels of Leu-$3^+8^-T_H$ may also exist within the paracortex in AIDS. These microenvironmentally specific findings may help to explain the follicular hyperplasia and polyclonal hypergammaglobulinemia that is present in many homosexual patients.[1-8,10,11,18,29,36] One prior study of PGL patients noted a consistent reversal of the T_H-T_{cs} ratio to <1.0 within germinal centers.[23] This was not observed in any of our AIDS patients or in another study comparing the immunohistology of lymph nodes from AIDS and PGL patients.[9]

Nicholson et al[18] have demonstrated that the Leu-$3(T4)^+8^+$ subset is decreased in the peripheral blood of patients with PGL. Our study suggested a reduction of this same subset within the paracortex of lymph nodes from patients with AIDS (Table 6). Furthermore, we observed a reversal not only of the T_H-T_s ratio, but also of the T_c-T_s ratio (Table 3). Consistent with these findings, prior functional studies of peripheral blood cells have documented increased in vitro suppressor activity in patients with AIDS or PGL.[6,18] The Leu-$3^+8^+T_H$ subset is reactive in the autologous mixed lymphocyte reaction and has a major role in the induction of delayed type hyersensitivity and the induction of T_s.[18,27] Some of these T_s may act as intermediaries in the suppression of B cell immunoglobulin synthesis.[18,27] In light of these functional characteristics, the decreased Leu-$3^+8^+T_H$, decreased T_c, and increased T_s documented within the paracortex of the AIDS cases are consistent with the defective cell-mediated immunity documented previously in AIDS.[1-16] The hypergammaglobulinemia and plasmacytosis previously noted in such patients[1-11,18,29,36] may be related to defective induction of those T_s concerned with the down regulation of humoral immunity.

Within the paracortex, the AIDS patients exhibited reduced Leu-8^+ cells (Table 4). It has been proposed that quantitation of novel subsets in homosexual patients may be of greater value than Leu-3^+-Leu-2^+ ratios in predicting clinical outcome.[18] Results from the seven AIDS patients offer some support of this possibility when supplemented with unpublished data from two patients with PGL and one heterosexual man who died of posttransfusion AIDS. Despite similar Leu-3^+-Leu-2^+ ratios in these ten patients, the two terminal AIDS patients had the lowest levels of Leu-8^+ cells, whereas the two patients with PGL had the eighth and ninth highest levels of Leu-8^+ cells. Similar trends were noted for total (Leu-4^+) T cells.

Considerable evidence now exists that HTLV-III/LAV retrovirus, which is cytotropic and cytopathic for Leu-3^+T_H, is the etiologic agent of AIDS and PGL.[44,45] The Leu-3 antigen is an essential component of the cell surface receptor necessary for HTLV-III/LAV infection.[44] Recent evidence also indicates that the Leu-8 antigen may somehow be involved in retroviral reception and penetration.[44] This may help to explain our current data that suggest that Leu-$3^+8^+T_H$ are markedly depleted in AIDS.

It will be important to determine whether the T cell subset alterations detected with anti–Leu-8 and 9.3 in this study are unique to AIDS or are also typical of other diseases associated with a decreased Leu-3^+-Leu-2^+ ratio. These refinements in our ability to dissect and quantitate T cell subsets in situ may prove to be useful in establishing the diagnosis, prognosis, and pathogenesis of immunodeficiency diseases.

Temperature-Dependent Effects of EDTA on the Membrane Glycoprotein IIb-IIIa Complex and Platelet Aggregability

by Dominique Pidard, Dominique Didry, Thomas J. Kunicki, and Alan T. Nurden

In agreement with previous studies, we observed that incubation of washed human platelets with EDTA at 37 °C for short periods caused an irreversible loss of their aggregation response to adenosine diphosphate and markedly diminished their capacity to bind fibrinogen. AP-2 is a monoclonal antibody that reacts with a determinant specific to the glycoprotein (GP) IIb-IIIa complex. We now report that in a direct binding assay, the number of sites for AP-2 on platelets incubated with EDTA at 37 °C fell to ~30% of those present on control platelets. This effect of EDTA was not observed at room temperature. Analysis of the treated platelets by sodium dodecyl sulfate-polyacrylamide gel electrophoresis revealed normal amounts of GP IIb and GP IIIa. However, studies using crossed immunoelectrophoresis with ^{125}I-AP-2, ^{125}I-Tab (anti-GP IIb), or ^{125}I-AP-3 (anti-GP IIIa) in intermediate gels showed that at 37 °C, EDTA was inducing an irreversible change in GP IIb-IIIa complexes. A reduction in size and probable dissociation of the GP IIb-IIIa precipitate was accompanied by the appearance of precipitates having the characteristics of those given by free GP IIb and free GP IIIa and the location of a major new cathodal precipitate, which bound Tab and AP-3 but not AP-2. Membrane modifications associated with the loss of antigenic determinants on GP IIb-IIIa may explain EDTA-induced loss of platelet aggregability at 37 °C.

PLATELETS ACTIVATED by adenosine diphosphate (ADP) and other physiologic stimuli express specific and saturable receptors for fibrinogen.[1] Binding of fibrinogen requires divalent cations and is correlated with the onset of platelet aggregation.[2-4] Growing evidence suggests that divalent cation-dependent complexes of two membrane glycoproteins (GP), IIb and IIIa, play an essential role in fibrinogen receptor expression and therefore in the aggregation process.[5-7] Part of this evidence has accumulated from studies with monoclonal antibodies such as AP-2[8] and T10,[9] which react with complex-dependent epitopes on GP IIb-IIIa and inhibit both fibrinogen binding to stimulated platelets and platelet aggregation. Other such antibodies have recently been catalogued.[10]

That GP IIb and GP IIIa may form complexes in the presence of Ca^{2+} was first shown in studies in which Triton X-100 extracts of platelets or isolated membranes were analyzed by crossed immunoelectrophoresis (CIE). A major immunoprecipitate was observed that, after divalent cation chelation with EDTA, was replaced by two new precipitates, one containing GP IIb and the other, GP IIIa.[5,11,12] Other studies on the extracted glycoproteins showed the complex to be a heterodimer[13,14] and that the complexes can bind ^{45}Ca^{2+},[15] possibly through GP IIb.[16] Indeed, they may represent the major calcium-binding site on the platelet surface[17,18] and participate in the transport of this cation across the plasma membrane.[19] Binding studies performed with the monoclonal antibodies AP-2[8] and T10[9] have confirmed the presence of the heterodimer in the membrane of inactivated platelets.

The results of studies by Zucker and Grant[20,21] showed that platelets incubated at 37 °C for short periods with EDTA subsequently failed to aggregate when challenged with ADP. The EDTA-treated platelets were unable to bind fibrinogen in the presence of ADP and exhibited a reduced capacity to bind ^{45}Ca^{2+}.[4,17] Recent advances in our knowledge of fibrinogen receptor expression suggest that EDTA may be acting on the GP IIb-IIIa heterodimers. To investigate this possibility, we have examined the effect of incubating platelets with EDTA at 37 °C, studying in parallel (a) platelet aggregation and fibrinogen binding, (b) AP-2 binding, and (c) GP IIb-IIIa stability. Results show that at 37 °C and alkaline pH, EDTA directly influences the structure of the IIb-IIIa heterodimers in the platelet membrane.

MATERIALS AND METHODS

The following materials were obtained commercially: prostaglandin E$_1$ (PGE$_1$), grade I apyrase, bovine serum albumin (BSA, fraction V), *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES), ADP, phenylmethylsulfonyl fluoride (PMSF), and synthetic hemisulfate leupeptin were from Sigma Chemical Co (St Louis); ethylenediamine tetraacetic acid disodium salt (EDTA) from Prolabo (Paris); purified human fibrinogen from Kabi Diagnostics (Stockholm); ^{125}I-fibrinogen was obtained from the Service des Radioisotopes of the Centre National de Transfusion Sanguine (Paris); Na^{125}I from the Centre de l'Energie Atomique (Orsay, France); agarose HSA type from Litex (Glostrup, Denmark); Triton X-100 from BDH Chemicals Ltd (Poole, England); glycine, tris (hydroxymethyl)aminomethane (Tris), sodium dodecyl sulfate (SDS), acrylamide, bisacrylamide, ammonium persulfate, 2-mercaptoethanol, TEMED, and Coomassie blue R-250 (CB-R) from Bio-Rad (Richmond, Calif). All other chemicals were of reagent grade. The monoclonal antibodies Tab[9,22] and AP-3[23] were kindly provided as purified IgG by Dr R. McEver (The University of Texas Health Science Center, San Antonio, Tex) and Dr P.J. Newman (The Blood Center of Southeastern Wisconsin, Milwaukee), respectively.

Platelet isolation. Blood (6 vol) was obtained from adult human volunteers and anticoagulated with acid-citrate-dextrose anticoagulant (ACD; NIH formula A) (1 vol).[24] Platelet-rich plasma prepared by centrifugation at 20 °C for 15 minutes at 120 g was acidified to pH 6.5 by addition of a one tenth vol ACD-A. PGE$_1$ (100 nmol/L) and apyrase (25 µg/mL) were also added. Washed platelets were prepared by the method of Patscheke[24] as modified by Legrand et al.[25] In the standard procedure, the platelets were washed in 36 mmol/L citric acid, 5 mmol/L glucose, 5 mmol/L KCl, 2 mmol/L CaCl$_2$, 1 mmol/L MgCl$_2$, 103 mmol/L NaCl, 3.5 mg/mL BSA, 100 nmol/L PGE$_1$, 25 µg/mL apyrase, pH 6.5 (washing buffer). Unless otherwise stated, the platelets were finally resuspended in a modified

Tyrode's solution consisting of 137 mmol/L NaCl, 2 mmol/L KCl, 12 mmol/L $NaHCO_3$, 0.3 mmol/L NaH_2PO_4, 2 mmol/L $CaCl_2$, 1 mmol/L $MgCl_2$, 5.5 mmol/L glucose, 5 mmol/L HEPES, pH 7.4 (HBMT).

Incubation with EDTA. Twice-washed platelets were resuspended at 10^9/mL in HBMT or the same buffer lacking calcium and magnesium but containing 2 mmol/L EDTA (HBMT-EDTA). In some experiments, the concentration of EDTA was varied as detailed in the text. Both buffers also contained 100 nmol/L PGE_1 and 25 μg/mL apyrase. The platelet suspensions were incubated at 20 °C or 37 °C for periods of up to 15 minutes in a thermostatically controlled water bath. Control incubations were performed in HBMT alone. After the incubation, the platelet suspensions were diluted with 5 vol washing buffer, centrifuged, and the platelets were resuspended at room temperature in HBMT containing 3.5 mg/mL BSA but lacking apyrase and PGE_1. To standardize the experimental conditions, all subsequent studies were started 30 minutes after the final platelet resuspension. Such platelets are subsequently referred to as "pretreated" platelets.

Platelet aggregation. Normal or pretreated washed platelets in HBMT were adjusted to 3×10^8 platelets per milliliter. Platelet aggregation was studied photometrically using a Labintec aggregometer (Central Labo, Paris). The platelet suspension (0.36 mL) was stirred (1,100 rpm) at 37 °C in the presence of 0.2 mg/mL fibrinogen and 5 or 10 μmol/L ADP. Changes in light transmission were continuously recorded and compared with the maximal change observed with HBMT buffer alone.

Fibrinogen binding assay. The binding of purified human ^{125}I-fibrinogen to ADP-stimulated control and EDTA-pretreated platelets was measured according to the procedure of Legrand et al.[26] The characteristics of the ^{125}I-fibrinogen preparation have already been reported.[26] Briefly, the assay was performed as follows: 0.4-mL vol of a washed platelet suspension in HBMT (5 to 8×10^8 platelets per milliliter) were mixed with 80 μL of HBMT and 40 μL of a 12 μmol/L solution of ^{125}I-fibrinogen in HBMT to give a final concentration of 1 μmol/L, at which steady-state binding of fibrinogen to its platelet receptor reaches saturation under our experimental conditions.[26] Binding was initiated three minutes later by adding 30 μL of a 200-μmol/L solution of ADP dissolved in HBMT to give a final concentration of 10 μmol/L, and continued for 30 minutes at room temperature, before triplicate samples of 0.15 mL were layered onto 0.5 mL of an inert oil mixture ($d = 1.014$).[26] The samples were centrifuged for three minutes at 12,000 g in an Eppendorf model 5414 centrifuge (Brinkman Instruments, Inc, Westbury, NY). Supernatants and pellets were fractionated and their associated ^{125}I-radioactivity measured in a Gamma 7000 counter (Beckman Instruments, Inc, Fullerton, Calif). Nonspecific binding of ^{125}I-fibrinogen was defined as that observed in the presence of a 20-fold excess of unlabeled fibrinogen initially added in a 80-μL vol instead of the buffer alone (see above). It represented approximately 35% of the total binding, from which it was substracted to give the specific binding.

AP-2 binding assay. AP-2 was isolated from ascites fluid and the monoclonal IgG labeled with ^{125}I using the chloramine T method.[8] The assay for the direct binding of ^{125}I-labeled antibody to washed platelets was adapted from that previously used by us.[8] Briefly, normal or pretreated washed platelet suspensions were first adjusted to 10^8 platelets per milliliter with HBMT. In the standard assay, aliquots (0.3 mL) were then mixed with near-saturating concentrations of ^{125}I–AP-2 (≥3 μg/mL). For Scatchard analysis (see ref. 8), aliquots were mixed with increasing amounts of ^{125}I–AP-2 (0.5 to 5.0 μg/mL) as detailed in the text. After a 30-minute incubation at room temperature, 0.14-mL samples were layered in duplicate over 0.5 mL 20% (wt/vol) sucrose in HBMT. Platelets were pelleted by centrifugation at 12,000 g for two minutes in an Eppendorf centrifuge. Each supernatant was aspirated and the radioactivity in both supernatants and pellets measured in a Beckmann 7000 gamma counter. Nonspecific binding was measured in the presence of a 50-fold excess of unlabeled AP-2. As this was found to be negligible (≤3% of total binding), the data is presented as total binding.

Crossed immunoelectrophoresis. Pretreated platelets resuspended in HBMT were diluted with 5 vol washing buffer and the platelets sedimented. The pellets were resuspended in 0.1 mol/L glycine, 0.038 mol/L Tris, pH 8.7 (Tris-glycine) prechilled to 4 °C. Platelet solubilization was performed at 4 °C by incubation for 30 minutes with 1% (vol/vol) Triton X-100. In selected experiments, the solubilization step was performed in the additional presence of 500 μg/mL leupeptin and 1 mmol/L PMSF. The Triton X-100 insoluble material was removed by ultracentrifugation and the supernatants stored at −80 °C until use. CIE was performed according to the procedures detailed by Kunicki et al[5] and Pidard et al.[8] Briefly, first-dimension electrophoresis was performed at 10 V/cm for one hour in 1% (wt/vol) agarose containing 0.5% (vol/vol) Triton X-100 in Tris-glycine. Second-dimension electrophoresis was performed at 2 V/cm for 18 hours into a biphasic gel system consisting of (a) an intermediate gel containing 1% agarose, 0.5% Triton X-100 and, on occasion, trace amounts of ^{125}I–AP-2, ^{125}I-Tab or ^{125}I–AP-3 and (b) an upper gel containing precipitating concentrations of a polyspecific rabbit antihuman platelet antibody preparation. Further experimental details are given in the figure legends. Immunoprecipitates were located by Coomassie blue R250 (CB-R) staining, and those containing ^{125}I, by autoradiography.[5,8]

SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Pretreated platelets in HBMT were pelleted and resuspended at 2×10^9/mL in 10 mmol/L Tris-HCl, 150 mmol/L NaCl, 3 mmol/L EDTA, pH 7.0, and solubilized by heating at 100 °C for five minutes after the addition of a one fifth vol of 12% (wt/vol) SDS containing 30 mmol/L *N*-ethylmaleimide. Aliquots of Triton X-100–soluble platelet extracts were diluted with an equal vol of 10 mmol/L Tris-HCl, 150 mmol/L NaCl, 3 mmol/L EDTA, pH 7.0, before being treated similarly. Triton X-100–insoluble material was resuspended in the same buffer before SDS solubilization. Samples were prepared with (reduced) or without (nonreduced) disulfide reduction, and electrophoresis was performed using 7% or 6% acrylamide rod gels, or 7% to 12% gradient acrylamide slab gels, according to the procedures detailed by Nurden et al.[27] Glycoproteins were located by periodic-acid Schiff (PAS) staining, and proteins, by CB-R staining. Densitometric scanning of PAS-stained rod gels was performed using a Vernon Integrating Photometer (Vernon Integrating Photometers Ltd, Paris). In some experiments, membrane glycoproteins were labeled with ^{125}I using the lactoperoxidase-catalyzed procedure detailed by Nurden et al[27] before the platelets were exposed to EDTA. ^{125}I-labeled polypeptides were revealed by autoradiography of dried polyacrylamide slab gels as previously described by us.[27]

RESULTS

Experimental conditions. The aim of this study was to examine the effect of controlled incubation with EDTA on the platelet aggregation response and on the GP IIb–IIIa complex. All platelet washing steps were therefore performed in the presence of divalent cations but at pH 6.5, to prevent the formation of platelet aggregates during centrifugation. Incubations at 37 °C were performed at pH 7.4 in the presence of (a) apyrase to prevent platelets becoming refractory to released ADP[28] and (b) PGE_1 to help maintain platelet integrity and inhibit granule release.[29]

Platelet aggregation. Washed human platelets that had been incubated for 15 minutes at 37 °C with 2 mmol/L EDTA failed to aggregate when resuspended in HBMT containing divalent cations and stimulated by ADP in the presence of added fibrinogen. A typical experiment is shown in Fig 1. Platelets that were incubated at 37 °C under control conditions in the presence of 2 mmol/L $CaCl_2$ and 1 mmol/L $MgCl_2$ were normally aggregated. Incubation of the platelets at 37 °C with equimolar amounts of Ca^{2+} and EDTA (CaEDTA-treated platelets) did not affect platelet aggregability. This suggested that the primary effect of EDTA was to chelate membrane-bound calcium. The phenomenon was time and temperature dependent. Incubation of platelets with 2 mmol/L EDTA for 15 minutes at 20 °C did not result in a loss of aggregability. Incubation of platelets with 2 mmol/L EDTA for shorter periods at 37 °C resulted in partial inhibition of the aggregation response (not shown). We also consistently observed a reduced "swirling" phenomenon in the final suspensions of unstimulated EDTA-treated platelets when compared with the control preparations. This may indicate a loss of their discoid shape during exposure to EDTA at 37 °C, a phenomenon previously described for EDTA-treated platelets by White.[30] In agreement with this conclusion, aggregation studies performed at lower concentrations of EDTA-treated platelets (1×10^8/mL) did not show the typical decrease in light transmission that normally follows the addition of ADP to stirred platelet suspensions and that reflects the change from disk-shaped to spherical platelets with pseudopods (not shown).

Fibrinogen binding. Control and EDTA-treated platelets were next compared as to their ability to bind ^{125}I-fibrinogen when activated with 10 μmol/L ADP in HBMT containing divalent cations. In experiments performed using platelets from four donors, the specific ADP-induced binding of fibrinogen to platelets preincubated at 37 °C under control conditions was 372 ± 130 ng fibrinogen per 10^8 platelets. In contrast, platelets of the same donors preincubated with 2 mmol/L EDTA for 15 minutes at 37 °C bound only 162 ± 90 ng fibrinogen per 10^8 platelets (mean ± SD). Thus fibrinogen binding was reduced to approximately 43% of its normal value.

Monoclonal antibody binding. Platelets prepared for aggregation studies were also tested for their capacity to bind the monoclonal antibody AP-2. Using near-saturating concentrations of ^{125}I–AP-2,[8] we found that platelets preincubated at 37 °C for 15 minutes with 2 mmol/L EDTA bound only 29.7% of the amount of antibody that bound to platelets incubated at 37 °C under control conditions (Table 1). No such reduction was observed when platelets were treated with CaEDTA at 37 °C or with EDTA at 20 °C. Increasing the concentration of EDTA (10 mmol/L) or the duration of the incubation at 37 °C caused only a small additional fall in the number of AP-2 binding sites. For example, approximately 20% of the binding sites remained on platelets pretreated with 2 mmol/L EDTA for 45 minutes at 37 °C (data not shown).

Scatchard analysis after the incubation of washed platelets with increasing concentrations of ^{125}I–AP-2 (see Materials and Methods) showed that the platelets bound 39,388 ± 5,832 IgG molecules per platelet with an affinity Kd = 0.81 ± 0.21 nmol/L (mean ± SD, n = 9). These values were similar to those previously reported by us.[8] Preincubation of the washed platelets at 37 °C for 15 minutes under the control conditions did not significantly change the platelet capacity to bind AP-2 (Table 1). In a single experiment, platelets that had been treated with 2 mmol/L EDTA for 15 minutes at 37 °C were also incubated with varying concentrations of ^{125}I–AP-2. Here, Scatchard analysis showed that the number of AP-2 molecules that had bound had fallen to 17,950 per platelet with an affinity Kd = 1.02 nmol/L. The latter value was unchanged from that obtained for untreated platelets, thus EDTA was primarily affecting the number of AP-2 receptors.

Crossed immunoelectrophoresis. Platelets prepared for aggregation studies were also solubilized with 1% Triton X-100 and the soluble extracts analyzed by CIE. Initial experiments established that the pattern of immunoprecipitates obtained for platelets incubated at 37 °C under the control conditions was identical to that obtained for washed

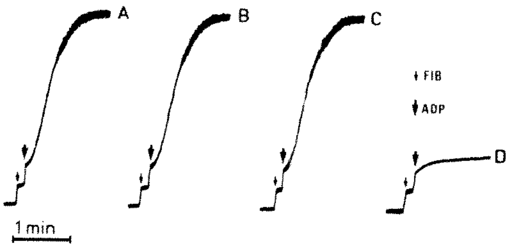

Fig 1. Irreversible inhibition of platelet aggregation by EDTA at 37 °C. Washed human platelets were incubated for 15 minutes (A) + 2 mmol/L Ca^{2+}, 1 mmol/L Mg^{2+} at 37 °C; (B) + 2 mmol/L Ca^{2+}, 2 mmol/L EDTA at 37 °C; (C) + 2 mmol/L EDTA at 20 °C; and (D) + 2 mmol/L EDTA at 37 °C. The platelets were sedimented and resuspended at 3×10^8 platelets per milliliter in HBMT. After 30 minutes, aliquots were tested for platelet aggregation induced by 10 μmol/L ADP in the presence of 0.2 mg/mL fibrinogen. Typical aggregation curves are shown.

Table 1. ^{125}I–AP-2 Binding to Pretreated Washed Platelets

Conditions of Incubation (15 min)	Amount of bound ^{125}I–AP-2 ng IgG/10^8 Platelets	 Percentage
2 mmol/L Ca^{2+}, 1 mmol/L Mg^{2+}; 20 °C	1,044 ± 126 (n = 3)	100.0
2 mmol/L Ca^{2+}, 1 mmol/L Mg^{2+}; 37 °C	1,176 (n = 1)	112.6
2 mmol/L Ca^{2+}, 2 mmol/L EDTA; 37 °C	1,130 (n = 2)	108.2
2 mmol/L EDTA; 20 °C	1,082 (n = 1)	103.6
0.5 mmol/L EDTA; 37 °C	330 (n = 2)	31.6
2.0 mmol/L EDTA; 37 °C	310 ± 97 (n = 4)	29.7
10.0 mmol/L EDTA; 37 °C	286 (n = 1)	27.4

The treated platelets were sedimented and resuspended at 1×10^8 platelets per milliliter in HBMT for the ^{125}I–AP-2 binding assay performed using ≥3 μg/mL AP-2 (see Materials and Methods). Results are expressed as the mean ± SD (where calculated) and as the percentage of the control incubation at 20 °C arbitrarily designated as 100%.

platelets prepared without pretreatment. In contrast, as shown in Fig 2, analysis of platelets that had been incubated for 15 minutes with 2 mmol/L EDTA at 37 °C revealed a marked reduction in the size of the immunoprecipitate given by the GP IIb–IIIa complex and the presence of a new, weakly stained precipitate in a more cathodal position (see next section). The use of small amounts of ^{125}I–AP-2 in the intermediate gel confirmed that the former precipitate contained GP IIb–IIIa but that no new AP-2 binding immunoprecipitates were present after the EDTA treatment. The area occupied by the GP IIb–IIIa precipitate on each plate was measured by planimetry and expressed relative to that of another major membrane antigen previously identified as GP IIIb.[5] The size and form of the GP IIIb containing immunoprecipitate was unchanged after platelet incubation with EDTA, and it therefore served as an internal standard. Table 2 shows that for three experiments, the apparent GP IIb–IIIa content of EDTA-treated platelets was about 39% of that present in platelets incubated under the control conditions. No such reduction was seen for platelets treated with EDTA at 20 °C or CaEDTA at 37 °C. A number of other immunoprecipitates located by CB-R staining are also identified in Fig 2. Neither GP Ib, highly sensitive to degradation by proteolytic enzymes,[31] nor α-granule proteins, such as fibrinogen, von Willebrand factor, and thrombospondin, appeared to have been modified during the platelet incubation at 37 °C. However, as an extra precaution against proteolysis, both the 37 °C pretreatment and the Triton X-100 solubilization steps were repeated in the additional presence of 500 μg/mL leupeptin and 1 mmol/L PMSF. The same apparent reduction in the GP IIb–IIIa content of the EDTA-treated platelets was observed.

Modification of GP IIb–IIIa in intact platelets by EDTA. Platelets that had been incubated with EDTA at 37 °C were solubilized with SDS and their glycoprotein composition analyzed by SDS-PAGE, followed by PAS staining. Densitometric scanning revealed that the GP IIb and GP IIIa content of EDTA-treated platelets was identical to that of platelets incubated at 37 °C under control conditions (data not shown). Thus EDTA was not causing the release of GP IIb or GP IIIa from the platelet surface. SDS-PAGE of the Triton X-100–soluble and –insoluble fractions also confirmed that GP IIb and GP IIIa were being normally solubilized by Triton X-100 from the EDTA-treated platelets.

One possible explanation for the effect of EDTA on AP-2 binding (Table 1) and platelet GP IIb–IIIa content (Fig 2) is that divalent cation chelation at 37 °C induces a dissociation of the complex in the platelet membrane. To investigate this possibility, CIE studies were performed using ^{125}I-Tab or ^{125}I–AP-3 in the intermediate gel. Tab is able to bind to free GP IIb,[9,22] and AP-3 reacts with free GP IIIa.[23] These antibodies, therefore, differ from AP-2, which recognizes a complex-dependent determinant.[8] Initial studies using ^{125}I-

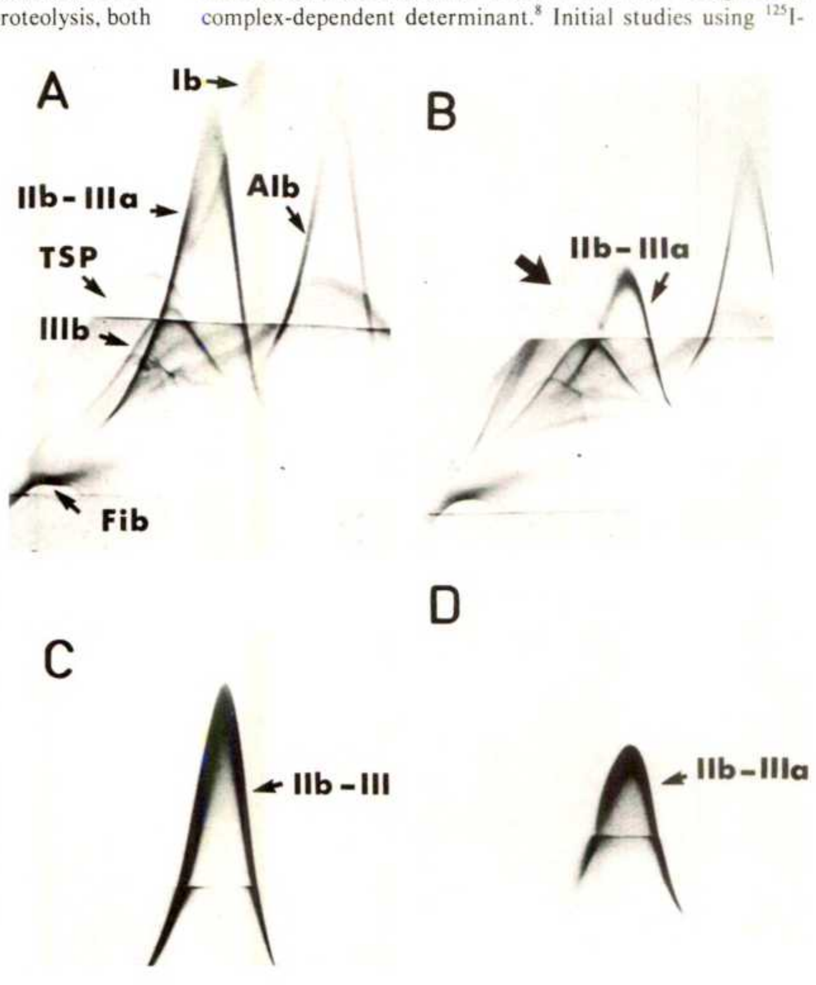

Fig 2. Reduced size of the GP IIb–IIIa immunoprecipitate on analysis of platelets incubated with EDTA at 37 °C. Washed human platelets were incubated for 15 minutes (A, C) + 2 mmol/L Ca^{2+}, 1 mmol/L Mg^{2+} at 37 °C, and (B, D) + 2 mmol/L EDTA at 37 °C. After sedimentation and resuspension in HBMT for 30 minutes, aliquots were prepared for CIE analysis (see Materials and Methods). Seventy micrograms of platelet protein solubilized in 1% Triton X-100 was electrophoresed from left to right in the first dimension. Electrophoresis in the second dimension was through an intermediate gel containing 3.5 × 10^5 cpm ^{125}I–AP-2. The upper gel contained 0.75 mg/cm^2 of polyclonal rabbit antihuman platelet antibody. In (A) and (B), immunoprecipitates were located by CB-R staining, and in (C) and (D), GP IIb–IIIa complexes that had bound AP-2 were detected by autoradiography. Note on (B) the appearance of a new precipitate, indicated by the heavy arrow. Alb, albumin; Fib, fibrinogen; TSP, thrombospondin.

Table 2. Quantitative Analysis of the GP IIb–IIIa Precipitate Obtained After CIE of Pretreated Washed Platelets

Conditions of Incubation (15 min)	Comparative Size of GP IIb–IIIa Precipitate	
	Ratio of GP IIb–IIIa to GP IIIb	Percentage
2 mmol/L Ca^{2+}, 1 mmol/L Mg^{2+}; 20 °C	2.92 ± 0.17 (n = 3)	100.0
2 mmol/L Ca^{2+}, 1 mmol/L Mg^{2+}; 37 °C	3.14 (n = 1)	107.5
2 mmol/L Ca^{2+}, 2 mmol/L EDTA; 37 °C	2.77 (n = 2)	94.9
2 mmol/L EDTA; 20 °C	3.68 (n = 1)	126.0
0.5 mmol/L EDTA; 37 °C	1.05 (n = 1)	36.0
2.0 mmol/L EDTA; 37 °C	1.13 ± 0.01 (n = 4)	38.7
10.0 mmol/L EDTA; 37 °C	0.88 (n = 1)	30.1

CIE of Triton X-100 extracts was performed as described in Fig 2. The area of the GP IIb–IIIa and GP IIIb precipitates was measured by planimetry and expressed as a ratio. Results are the mean ± SD (where calculated) and as the percentage of the control incubation at 20 °C arbitrarily designated as 100%.

Tab confirmed that only GP IIb–IIIa complexes were present in Triton X-100 extracts of platelets preincubated at 37 °C under control conditions (Fig 3) or with EDTA at room temperature (not shown). In contrast, when extracts of platelets that had been treated with EDTA at 37 °C were analyzed, two, or sometimes three, immunoprecipitates were labeled with the antibody. The first of these corresponded to that given by residual GP IIb–IIIa complexes and was identical to that which bound AP-2 (see Fig 2). The second was the new cathodal immunoprecipitate previously noted to be present on CB-R–stained gels and that clearly shows a line of antigenic identity to GP IIb–IIIa (Fig 3B) but which did not bind AP-2. This was a surprise, for previous studies had shown dissociated GP IIb to be present exclusively in an immunoprecipitate located directly above that containing residual GP IIb–IIIa.[5] Such an immunoprecipitate was occasionally observed (open arrow in Fig 3B). However, its presence was often difficult to confirm due to the intense labeling of the residual GP IIb–IIIa precipitate by ^{125}I-Tab. Figure 3 also shows CIE studies performed with ^{125}I-Tab in the intermediate gel when Triton X-100 extracts of the EDTA-treated platelets were made 5 mmol/L with EDTA and further incubated for 15 minutes at room temperature just before the CIE. These are conditions known to induce a dissociation of Triton X-100–solubilized GP IIb–IIIa heterodimers.[5] The precipitate containing free GP IIb[5] was now increased in size (Fig 3C), while that given by the residual GP IIb–IIIa complexes was decreased. By continuing the second incubation at room temperature for one hour, a total dissociation of residual GP IIb–IIIa was obtained (not shown). However, no modification in either the location, the shape, or the ^{125}I-Tab labeling intensity of the new cathodal precipitate was observed under these conditions.

^{125}I–AP-3 also labeled three immunoprecipitates during CIE of extracts of platelets incubated with EDTA at 37 °C (Fig 3D). The major arc corresponded to that given by residual GP IIb–IIIa complexes. Of the two cathodal arcs reacting with ^{125}I–AP-3, one was identified as the new GP IIb–IIIa-related precipitate also labeled by ^{125}I-Tab. This

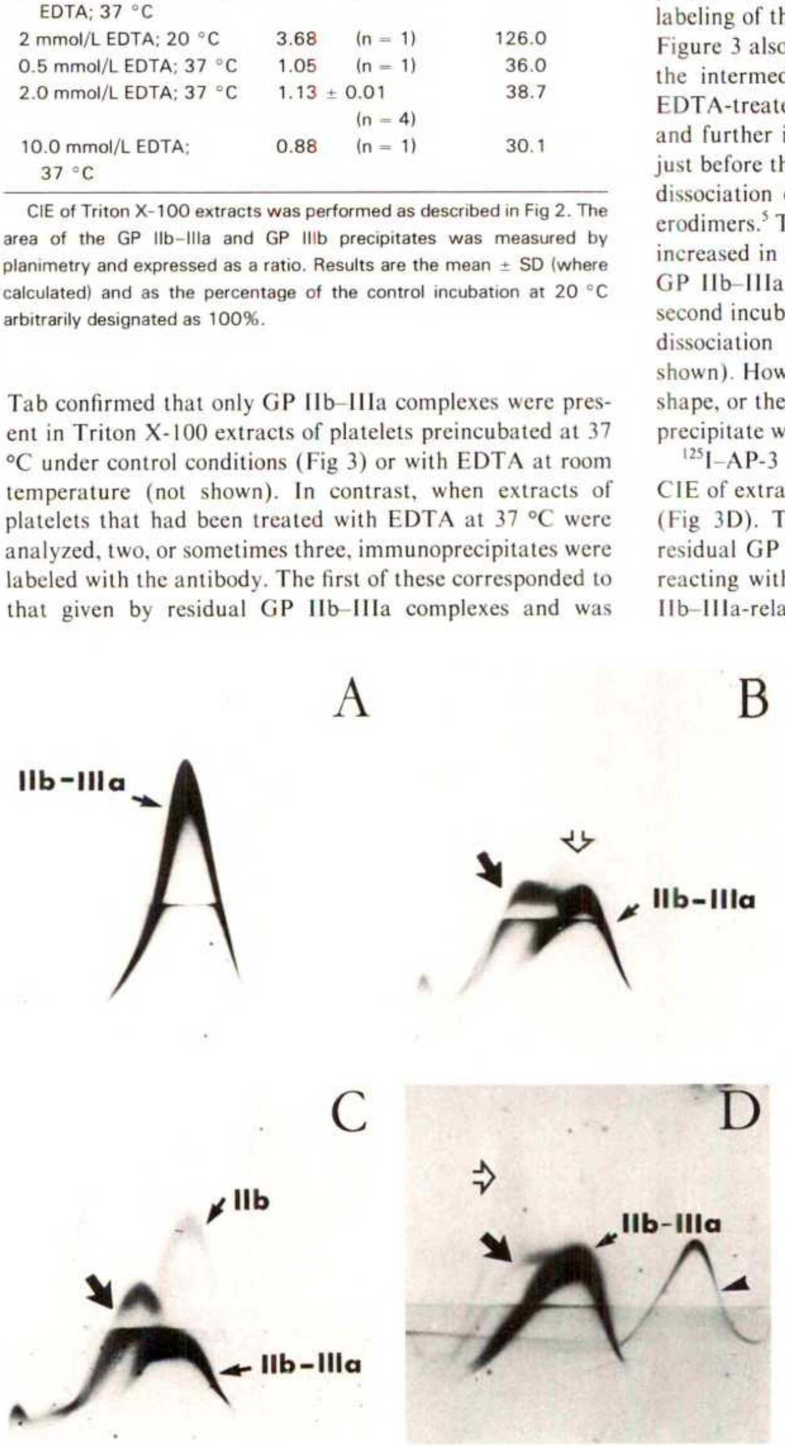

Fig 3. Temperature-dependent alterations in GP IIb–IIIa complexes by EDTA. Washed human platelets were incubated for 15 minutes at 37 °C (A) + 2 mmol/L Ca^{2+}, 1 mmol/L Mg^{2+} or (B, C, D) + 2 mmol/L EDTA and processed as described in Fig 2. CIE was performed with 3.5 × 10^5 cpm ^{125}I-Tab (A, B, C) or ^{125}I–AP-3 (D) in the intermediate gel. In (C), an identical Triton X-100–soluble extract to that in (B) was further incubated with 5 mmol/L EDTA at 20 °C for 15 minutes immediately before the first-dimension electrophoresis. Typical autoradiographs are shown. In (B) and (D), the open arrows indicate the location of free GP IIb and free GP IIIa, respectively. The arrow head in (D) points to the precipitate given by platelet albumin that was visualized as a result of traces of ^{125}I-labeled serum albumin that contaminated the ^{125}I–AP-3 preparation.

conclusion was based on its size, shape, and line of partial antigenic identity with the IIb-IIIa precipitate (compare Fig 3B and D). The third component (open arrow in Fig 3D) exhibited the features previously reported for free GP IIIa on CIE analysis, ie, a slower electrophoretic mobility than the GP IIb–IIIa heterodimer, leading to a more cathodal precipitate[5,23] and an absence of reactivity with ^{125}I-Tab[9] and ^{125}I–AP-2.[8]

The presence of both GP IIb and GP IIIa within the new cathodal immunoprecipitate was confirmed by SDS-PAGE analysis after excision and SDS solubilization of this particular precipitation line from unstained agarose gels, according to the procedure previously detailed by Kunicki et al.[5] The study was performed with Triton X-100 extracts of platelets whose surface proteins had been labeled with ^{125}I by the lactoperoxidase-catalyzed procedure before their incubation with EDTA at 37 °C. Autoradiograms of dried polyacrylamide gels revealed the presence of two ^{125}I-labeled components in this new immunoprecipitate, with nonreduced and reduced molecular weights identical to those of GP IIb and GP IIIa (not shown).

DISCUSSION

It is well known that divalent cations are essential cofactors of platelet aggregation. Zucker and Grant[20,21] highlighted a special case when they described how pretreatment of platelet-rich plasma with EDTA at 37 °C resulted in an irreversible loss in the platelet aggregation response to ADP. This effect of EDTA was temperature dependent, occurring at 37 °C but not at 20 °C, and was only observed at alkaline pH (>pH 7.2). Aggregation induced by epinephrine and the ionophore A 23187 was also inhibited, and although the treated platelets were aggregated by thrombin, the velocity of aggregation was decreased. The subsequent observations that washed platelets incubated with EDTA at 37 °C (a) had a reduced capacity to bind $^{45}Ca^{2+}$[17] and (b) bound little or no fibrinogen in the presence of ADP and calcium[4] suggested that EDTA was influencing a crucial step at a late stage of the aggregation mechanism.

In confirming the temperature-dependent inhibitory effect of EDTA on the platelet aggregation response, we have shown that it is accompanied by structural changes in the GP IIb–IIIa complex. One manifestation of these changes was an irreversible fall in the number of AP-2 binding sites expressed by platelets treated with EDTA at 37 °C and alkaline pH. Significantly, this fall was of similar magnitude to the loss in the ability of the platelets to bind fibrinogen after ADP stimulation. The binding of AP-2 to GP IIb-IIIa complexes of normal platelets is followed by the inhibition of both platelet aggregation and fibrinogen binding after platelet activation.[8] As increasing evidence suggests that GP IIb–IIIa complexes constitute the fibrinogen receptor on the platelet surface,[1,6-9] it is probable that the reduced binding of both AP-2 and fibrinogen after incubation of platelets with EDTA at 37 °C are related events.

Our results with AP-2 may be compared with those reported by Coller et al,[32] using the monoclonal antibody 10E5, and those of Brass et al,[33] who used another antibody, A2A9. Both 10E5 and A2A9 appear to react with complex-dependent determinants on GP IIb–IIIa. Coller et al[32] observed a 51% reduction in the amount of 10E5 that bound to platelets after citrated platelet-rich plasma had been incubated with EDTA at pH 8.3 for 15 minutes at 37 °C. In contrast, Brass et al[33] reported a complete loss in the binding of A2A9 to gel-filtered platelets incubated with EDTA for one hour at 37 °C and pH 7.4. However, the binding of AP-2, 10E5, or A2A9 was not affected by EDTA when the temperature and pH of the incubation medium were kept within the ranges of 20 to 25 °C and pH 7.4 to 7.8, respectively.[8,32,33] Nonetheless, under these conditions, the binding of a newly described monoclonal antibody, 7E3, was decreased by more than 40%.[32] Finally, the binding of another anti-GP IIb–IIIa monoclonal antibody, T10, was reduced after the incubation of gel-filtered platelets for 30 minutes at room temperature and at pH 8.5.[9] Subtle differences in the specificity of the different antibodies for their determinants on GP IIb–IIIa probably account for the variations, which may also reflect progressive changes in the conformation or organization of the complexes during platelet incubation with EDTA at different pH and temperatures.

CIE experiments confirmed a direct temperature-dependent effect of EDTA on GP IIb–IIIa complexes in the platelet membrane. This was first observed as a reduction in the size of the immunoprecipitate containing GP IIb–IIIa. The good correlation between the extent of the EDTA-induced loss of AP-2 binding sites on intact platelets at 37 °C and the reduction in size of the GP IIb–IIIa precipitate strongly suggests that the changes observed after CIE did not arise subsequent to the platelet solubilization step, a view also supported by the fact that solubilization with Triton X-100 was performed under conditions that might stabilize preexisting IIb–IIIa heterodimers, ie, at low temperature and in the presence of Ca^{2+} released from disrupted organelles.[5]

The labeling by both Tab and AP-3 of a second major immunoprecipitate in a more cathodal position to GP IIb–IIIa during CIE of Triton X-100–soluble extracts of platelets that had been preincubated with EDTA at 37 °C was unexpected. These monoclonal antibodies react with EDTA-resistant determinants on GP IIb[9,22] and GP IIIa,[23] respectively. The results of studies performed after the incubation of Triton X-100–soluble platelet extracts with EDTA at 4 °C or 20 °C have shown that free GP IIb migrated at a rate similar to that of the GP IIb–IIIa complexes in the first-dimension electrophoresis, while dissociated GP IIIa gave a more cathodal immunoprecipitate.[5,11,12] Furthermore, any decrease in the precipitate given by GP IIb–IIIa due to a dissociation of the complex was directly compensated for by an increase in the arcs given by free GP IIb and free GP IIIa.[5] However, although small amounts of free GP IIb and free GP IIIa were visualized on CIE analysis of platelets pretreated with EDTA at 37 °C, the bulk of GP IIb and GP IIIa not present in the heterodimer precipitate was located within the new cathodal arc. Re-addition of EDTA to the Triton X-100–soluble extracts prepared from platelets pretreated with EDTA at 37 °C resulted in dissociation of residual GP IIb–IIIa complexes and the increased appearance of ^{125}I-Tab- or ^{125}I-AP-3-labeled arcs in the position of free GP IIb and free GP IIIa (data not presented). In contrast, the antigens within the new major cathodal immunoprecipitate were not sensitive to further EDTA treatment. Thus it appears that this precipitate contains GP IIb and GP IIIa reorganized into a new common structure that specifically forms under conditions of low calcium concentration and elevated temperature and that lacks the IIb–IIIa heterodimer-specific epitopes recognized by antibodies such as AP-2. The fact that the glycoproteins within this precipitate have a more cathodal migration is suggestive of polymer formation. That this may be so is also suggested by the parallel studies of Shattil et al[34] and Fitzgerald and Phillips.[35] These authors have described populations of GP IIb–IIIa complexes solubilized from platelets treated with EDTA at 37 °C that showed electrophoretic properties in polyacrylamide gels under nondenaturing conditions[34] or sedimentation profiles after centrifugation across sucrose density gradients[35] that were indicative of the presence of high-molecular-weight aggregates.

The temperature dependence of the EDTA effect is striking. As temperature has only a limited effect on the chelating capacity of EDTA (see ref. 19), it appears that another explanation is required. One possibility is that some of the Ca^{2+} binding sites located on GP IIb or GP IIIa[15-18] are only accessible to EDTA at 37 °C, perhaps due to temperature-dependent membrane fluidity changes.[36] This may then lead to dissociation of GP IIb–IIIa complexes, followed by the recombination of the monomeric glycoproteins into high-molecular-weight aggregates lacking the structural specificities of the heterodimers. Alternative effects of EDTA also cannot be excluded. These could involve the undetected solubilization of loosely bound peripheral membrane proteins important for GP IIb–IIIa organization or stimulation of membrane enzymatic activities leading to degradation or cross-linking of GP IIb and GP IIIa. However, the observed lack of inhibition by leupeptin and the normal migration of GP IIb and GP IIIa on SDS-PAGE would seem to rule out both an effect of the major platelet Ca^{2+}-dependant protease[31,37] and a covalent bonding of separated polypeptide chains.

In conclusion, our studies point to a temperature-dependent effect of EDTA on GP IIb–IIIa complexes, which may explain the loss of aggregability of the treated platelets through their inability to bind fibrinogen after platelet activation. As such, our results differ from those recently presented by Zucker et al,[38] who also examined the behavior of GP IIb and GP IIIa in Triton X-100–soluble extracts of human platelets incubated with EDTA at 37 °C. These authors showed the presence of GP IIb–IIIa complexes in Triton X-100 extracts of membranes prepared from the EDTA-treated platelets but did not quantitate the levels of GP IIb–IIIa present or examine the intact platelets in antibody binding studies. The effect of EDTA on GP IIb–IIIa appears to be subtle. However, the changes appear to concern functionally important regions of the complex, and thus EDTA treatment may represent a useful approach to elucidating the role of this complex in the responses of platelets to activation.

Pathogenesis of B Cell Lymphoma in a Patient With AIDS

By Jerome E. Groopman, John L. Sullivan, Carel Mulder, David Ginsburg, Stuart H. Orkin, Carl J. O'Hara, Kenneth Falchuk, Flossie Wong-Staal, and Robert C. Gallo

Lymphoma occurs at increased frequency in patients with the acquired immunodeficiency syndrome (AIDS). We studied, using serologic and molecular techniques, one such lymphoma for (a) evidence of infection with human T lymphotropic virus, type III (HTLV-III), and Epstein-Barr virus (EBV), (b) monoclonal rearrangement of immunoglobulin and T cell receptor genes, and (c) rearrangement of the c-myc oncogene. Immunoglobulin and T cell receptor gene studies demonstrated that the tumor was of monoclonal B cell origin. Similar to cases of Burkitt's lymphoma unrelated to AIDS, there were DNA sequences in the lymphoma that hybridized to EBV-specific probes and demonstrated evidence of c-myc rearrangement. HTLV-III sequences were not detected in the malignant B cells. The pathogenesis of some B cell neoplasms in patients with the syndrome may involve transformation by EBV and deregulation of oncogene expression without direct infection of the malignant B cells by HTLV-III.

© 1986 by Grune & Stratton, Inc.

THE ACQUIRED IMMUNODEFICIENCY syndrome (AIDS) is a transmissible disorder etiologically linked with infection by human T cell lymphotropic virus, type III (HTLV-III).[1–3] The major clinical manifestations of AIDS include opportunistic infections or opportunistic neoplasms, such as Kaposi's sarcoma and central nervous system lymphoma.[4] Recently, B cell lymphomas outside the central nervous system have been described in individuals with AIDS or among homosexual men epidemiologically at risk for the disorder.[5–9] We have studied the roles of HTLV-III, the Epstein-Barr virus (EBV), and the c-myc oncogene in the pathogenesis of a B cell lymphoma in a man with AIDS. Immunoglobulin plus T cell receptor gene studies were used to confirm monoclonal B cell origin. Our findings suggest that EBV potentiates the development of B cell neoplasia, while HTLV-III sets the immunosuppressive milieu but does not appear to infect the malignant B cells directly. Rearrangement of the c-myc oncogene occurred in this case similar to rearrangement in Burkitt's lymphoma unrelated to AIDS.

MATERIALS AND METHODS

The patient was a 43-year-old Hispanic man whose risk factor for AIDS was 20 years of multiple homosexual contacts. He was diagnosed as having AIDS by biopsy of a cutaneous lesion that revealed Kaposi's sarcoma. His major clinical manifestations of AIDS included unexplained fevers, diarrhea, and progressive dementia. No enteric pathogens or parasites were identified in his stool and an upper and lower endoscopy revealed Kaposi's sarcoma. The etiology of his dementia was not determined. Lumbar puncture revealed normal glucose of 58 mg/dL, elevated protein of 78 mg/dL, and 10 mononuclear cells per microliter. CT scan of the brain showed generalized atrophy, cultures of cerebrospinal fluid for bacteria, fungi, and mycobacteria were negative, and cytology was unremarkable. The patient died and an autopsy was performed. Sera were collected at multiple times during the course of his illness, and tissues were immediately cryopreserved at the time of death.

Complete blood count, total lymphocyte count, and T cell subsets were performed as previously described.[10] Antibodies to EBV early antigen, nuclear antigen, and viral capsid antigen were measured as previously described.[11] Antibodies to HTLV-III were measured by an enzyme-linked immunosorbent assay and Western electroblot technique.[12] Multiple sections of the B cell lymphoma were studied for EBV nuclear antigen using fluorescent techniques.[3] For immunoglobulin and T cell receptor gene studies, DNA was prepared from a biopsy specimen of the lymphoma, digested with the appropriate restriction enzyme and examined by Southern blot hybridization with the corresponding radiolabeled probe using standard methods, as previously described.[13] Immunoglobulin gene probes were as described by Korsmeyer et al[14]—J_H (2.4-kilobase [kb] sau3a fragment), C_K (2.5-kb *Eco*RI fragment), $C\ \lambda$ (0.8-kb *Bam*HI–*Hind*III fragment). T cell receptor gene probes were C_β (0.6-kb *Bgl*II–*Eco*RV fragment of YT35)[15] and $C\ \alpha$ (1.2-kb *Eco*RI fragment of clone V7d).[16]

DNA was also probed for sequences related to EBV, cytomegalovirus, and human T cell leukemia virus, types I, II, III, as well as for rearrangement of the c-myc oncogene.[3,16,17] The ontogeny of the tumor was studied by immunofluorescent staining of tissue sections using specific antisera to the immunoglobulin kappa and lambda light chains.

RESULTS

Autopsy revealed extensive replacement of lymph nodes by large cells with vesicular nuclei and nucleoli. Masses containing similar cell types were distributed throughout the gastrointestinal tract, liver, and spleen. The brain showed generalized loss of gray and white matter with inclusion bodies consistent with cytomegalovirus. No lymphoma was found in the brain. On light microscopy, the histology of the tumor was consistent with a diffuse large-cell lymphoma. Immunofluorescent studies for immunoglobulin light chains revealed a predominance of lambda light chains, suggesting a monoclonal origin. Immunoglobulin gene studies performed on DNA prepared from the lymphoma (Fig 1)

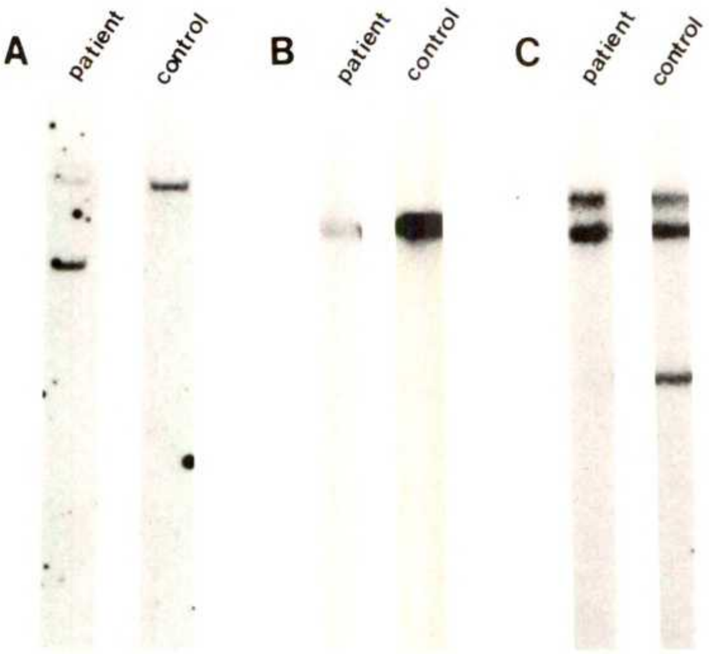

Fig 1. Detection of immunoglobulin gene rearrangement by Southern hybridization. DNA from a biopsy specimen of the patient's lymphoma was examined by Southern blot hybridization using immunoglobulin gene probes as described in Materials and Methods. In all three panels (A through C) the lymphoma DNA is shown in the first lane, with control DNA (from a normal unrelated individual) in the germline configuration in the second lane. Dashes indicate the expected position of germline bands.[14] (A) Immunoglobulin heavy chain locus (*Bam*HI/J_{H2} probe). A prominent rearranged band is evident at the lower arrowhead, consistent with a monoclonal B cell population. The absence of a second band of equal intensity suggests deletion of the second heavy chain locus in these cells. The faint persistent germline band may be due to a small amount of residual normal tissue in the biopsy specimen. The upper arrowhead marks a second faint rearranged band. This may represent incomplete detection of a rearrangement at the second heavy chain locus. We cannot exclude a rearrangement due to a second, smaller monoclonal cell population (a "biclonal" lymphoma). (B) Kappa light chain locus (*Bam*HI/C_κ). Only a faint germline band is evident in the lymphoma DNA. This is most consistent with deletion of both kappa gene loci, with the faint band due to residual normal tissue in the biopsy specimen, as above. (C) Lambda light chain focus (*Eco*RI/C λ). The absence of one germline band from the lymphoma DNA is evident. This pattern could be consistent with deletion or rearrangement of one lambda light chain gene. However, since nonlymphoid DNA from this patient was not examined, we cannot exclude the presence of a restriction fragment length polymorphism at the lambda light chain locus[14] as the explanation for this pattern.

revealed evidence for rearrangement at the heavy chain locus and probable deletion of both kappa light chain loci. Examination of the T cell receptor alpha and beta chain loci revealed exclusively the germline configuration with no evidence for clonal rearrangement (data not shown). This pattern is most consistent with monoclonal proliferation of B cell origin and of lambda light chain type. These results were in agreement with the immunofluorescent studies.

Serologic studies indicated antibodies to EBV early, nuclear, and capsid antigens, cytomegalovirus, and HTLV-III (Table 1). Antibodies to HTLV types I or II were not present. The tumor tissue expressed EBV nuclear antigen detected by immunofluorescence. Southern analysis revealed sequences related to EBV in the B cell lymphoma (Fig 2) but no hybridizing sequences using probes for cytomegalovirus, HTLV-III, HTLV-I, and HTLV-II. Rearrangement near the c-myc gene was also detected by Southern analysis (Fig 3).

DISCUSSION

B cell lymphomas occur with increased frequency in a variety of hosts with inherited or acquired deficiencies of the cellular immune system.[18-21] Considerable epidemiologic and molecular biologic data suggest that some of these B cell lymphomas are associated with the presence of circular EBV genome and possibly integration of EBV into host genome.[11,19] Polyclonal B cell hyperplasia is frequently found in lymph nodes of patients with AIDS or AIDS-related complex.[8] In some cases, there appears to be an initial

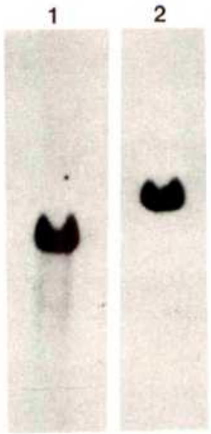

Fig 2. Detection of EBV DNA in lymphoma tissue by Southern hybridization. DNA (20 μg) extracted from lymphoma tissue obtained at autopsy was cleaved with *Bam*HI, subjected to electrophoresis (1.5 V/cm, 18 hours) through a 0.75% agarose gel and transferred to a nitrocellulose sheet. This gel replica was hybridized to PKD-52, a *Bam*W fragment of EBV in pBR322 (a gift from E. Kieff, University of Chicago, Chicago). Lane 1, 20 μg lymphoma DNA, lane 2, 30 pg pBR322 was added to 20 μg lymphocyte DNA from an EBV-seronegative control, equivalent to ten copies of viral DNA per cell. The hybridization in lane 2 is with pBR322 and not with EBV, as shown by different location of the hybridization band compared with lane 1.

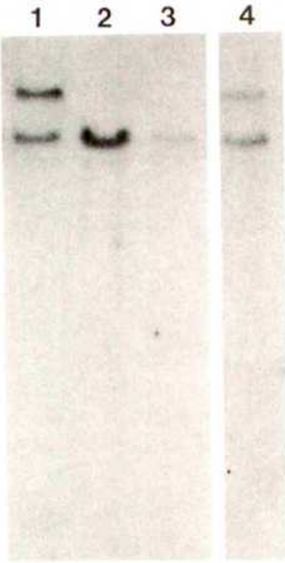

Fig 3. Detection of rearranged c-myc gene by Southern hybridization. Lymphoma tissue DNA (20 μg) was cleaved with *Eco*RI, the DNA fragments were separated by electrophoresis (1.7 V/cm, 18 hours) through a 0.75% agarose gel. The DNA was then transferred to cellulose nitrate under partial vacuum, fixed, and hybridized with ^{32}P-labeled 3rd exon of human c-myc (Hu 3′ myc, 1.2 kb, RI-*Cla*, 3rd exon) in pBR327 (Taub) (a gift from P. Leder, Harvard Medical School, Boston). Lane 1, Raji (Burkitt's lymphoma with detectable rearrangement of c-myc) cell DNA; lane 2, P3HR1 (Burkitt's lymphoma without detectable rearrangement of c-myc) cell DNA; lane 3, lymph node DNA from a fatal EBV infection in a patient with X-linked lymphoproliferative syndrome with a polyclonal, karyotypically normal EBV-induced B cell proliferation; lane 4, lymphoma tissue DNA from the AIDS patient.

polyclonal activation of B cells, followed by emergence of a monoclonal neoplasm. HTLV-III is the primary etiologic agent in AIDS.[1-3] The T4 antigen, or a closely related membrane antigen, appears to be necessary for entry and permissive infection of HTLV-III in T lymphocytes.[22,23] Because some activated B cells express the T4 antigen and, in vitro, HTLV-III can infect T4-bearing lymphoblastoid cell lines transformed by EBV, it is possible that HTLV-III could directly infect in vivo activated B cells and play a primary pathogenetic role in the development of B cell neoplasia in AIDS.[23] Our study of this case argues against such a model. There were no sequences related to HTLV-III in the B cell lymphoma, despite clear serologic evidence of HTLV-III infection in the host. A more likely model, based on our study, would be the emergence of an EBV-transformed B cell clone resulting from impaired cellular "immunologic surveillance" due to infection of T cells by HTLV-III.

Serologic studies in AIDS demonstrate high titers of antibodies to EBV antigens, suggesting reactivation of this virus in some patients.[5] Previous case reports have indicated chromosomal translocations t(8:14) and t(8:22) in B cell lymphoma in AIDS.[6,7] Such translocations occur in endemic (African) and nonendemic Burkitt's lymphoma.[24-26] Karyotype was not done in our case, but DNA rearrangement near the c-myc gene was detected. The c-myc oncogene is located on chromosome 8 and is rearranged in Burkitt's lymphoma unrelated to AIDS.[7] The pathogenesis of some B cell lymphoma in AIDS may involve initial polyclonal expansion of the B cell population due to reactivation of EBV with subsequent emergence of a transformed monoclonal population characterized by chromosomal rearrangement and disordered regulation of the c-myc oncogene. The emergence of the transformed clone may be facilitated by HTLV-III infection and impaired immune surveillance.

The Mutual Relationship Between the Two Molecular Forms of the Major Fibrinolysis Inhibitor Alpha-2-Antiplasmin in Blood

By C. Kluft, P. Los, A.F.H. Jie, V.W.M. van Hinsbergh, E. Vellenga, J. Jespersen, and Ch.P. Henny

Alpha-2-antiplasmin, a major inhibitor of fibrinolysis, is synthesized in the liver and occurs in blood in two molecular forms: a very active plasminogen-binding (PB) form and a less active nonplasminogen-binding (NPB) form. This study investigates the origin and mutual relationship of these two forms in vivo and in vitro. Despite wide variation in plasma concentration of the inhibitor (16% to 138%), the ratio between the two forms in vivo was found to be, in the main, constant among healthy volunteers, heterozygotes for a congenital deficiency of alpha-2-antiplasmin, and patients with a stable liver cirrhosis: PB/NPB = 2.41 ± 0.34 (SD). Resynthesis after depletion or increased synthesis in the acute-phase reaction showed a specific increase of the PB form of the molecule in blood after discontinuation of L-asparaginase or streptokinase therapy and after myocardial infarction. In vitro studies demonstrated that only the PB form was present after one day in the culture medium of the human cell line Hep G2, while the NPB form appeared after 11 days. Clearance after inhibition of synthesis by L-asparaginase therapy revealed a more rapid decrease in the PB form relative to the NPB form in blood, demonstrated by a change in the PB-NPB ratio from 2.86 ± 0.55 to 1.74 ± 0.24 (mean of 6, SD). An apparently spontaneous first order conversion from the PB to NPB form, with an apparent half-life of about eight days, was demonstrated at 37 °C in plasma and serum in vitro. The conversion was found to be temperature dependent and uninfluenced by the fibrinolytic components fibrinogen, fibrin, and plasminogen. Additions of a variety of enzymes or inhibitors did not interfere with the process. These results demonstrate that the PB form of alpha-2-antiplasmin is produced by the liver and that the NPB form is formed in the circulation.
© 1986 by Grune & Stratton, Inc.

ALPHA-2-ANTIPLASMIN is a plasma glycoprotein with an apparent molecular weight (mol wt) of 68,000.[1,2] It occurs in blood in two molecular forms: plasminogen binding (PB) and nonplasminogen binding (NPB).[3] The PB form inhibits plasmin-activated fibrinolysis by rapid formation of a stoichiometric plasmin complex.[2,4] It further interacts with fibrinolysis by forming a reversible complex with plasminogen and by covalent binding to fibrin during coagulation caused by the action of the fibrin stabilizing factor (factor XIII).[5,6] The NPB form reacts much more slowly with plasmin,[3] does not bind to plasminogen, and is not significantly cross-linked to fibrin.[7] Alpha-2-antiplasmin plays a critical role in the in vivo regulation of fibrinolysis, as shown by the hemorrhagic diathesis found in congenitally deficient patients[8-11] as well as in some heterozygotes.[9,10] This role is attributed to the PB form; the relevance of the NPB form is unknown.

The site of synthesis of alpha-2-antiplasmin appears to be the liver, as recently supported by demonstration of synthesis in an established liver cell line[12] and in rat hepatocytes.[13] It is unknown, however, which form of alpha-2-antiplasmin is synthesized and the mutual relationship of the two forms is unclear. Circumstantial evidence has been provided that the NPB form can be obtained from the PB form in vitro[14] and in vivo.[15]

To determine the origin and mutual relationship of the two forms of alpha-2-antiplasmin, we studied their occurrence and behavior under various conditions in blood and in culture media of a liver cell line with a recently devised assay for both forms.[16] The study provides data that demonstrates the synthesis of the PB form and the formation of the NPB form in the circulation.

MATERIALS AND METHODS

Materials. Unless otherwise specified, reagents were of analytical grade and obtained from Merck, Darmstadt, FRG. "Agarose for electrophoresis" (lot No. 33006) and iodoacetamide were obtained from BDH Chemicals Ltd, Poole, England. Carbowax 6000 was from Fluka AG, Buchs, Switzerland. Antiserum raised in rabbits against human alpha-2-antiplasmin was a gift from Dr I. Clemmensen, Copenhagen. Lys-plasminogen was prepared from human Cohn fraction III by affinity chromatography on lysine-agarose,[17] followed by gel filtration on Sephadex G-150. Trasylol (5880 KIU [kallikrein inactivator units]/mg) was a gift from Bayer AG, Wuppertal, FRG, through the courtesy of Dr E. Philipp. The synthetic tripeptide H-D-Val-Leu-Lys-pNA (S-2251) for plasmin was from AB Kabi, Stockholm.

Ellagic acid, actin was from Dade Diagnostics Inc, Miami. Dextran sulphate, sodium salt (mol wt 500,000) was obtained from Pharmacia Ltd, Uppsala, Sweden. Active Cls-esterase was prepared from outdated plasma according to Vroon et al[18] and Haines and Lepow.[19] Trypsin inhibitor from soybean type I-S, from turkey egg white type II-T and diisopropylphosphofluoridate (DFP) were from Sigma Chemical Co, St Louis. Lima bean trypsin inhibitor, ovoinhibitor, and ovomucoid were from Worthington Biochemical Corp, Freehold, NJ. Whole extracts of granula of polymorphonuclear granulocytes were prepared as described before.[20] Elastatinal, pepstatin, and chymostatin (see ref. 21) were gifts from Dr H. Umezawa, Microbiological Chemistry Research Foundation, Tokyo.

Plasma. Platelet-poor citrated human plasma and pooled plasma were prepared as described by Kluft et al[22]; serum was prepared by incubation of nonanticoagulated blood at 37 °C for four hours in plastic tubes before centrifugation. Factor XII- and factor XIII-deficient plasma were obtained from George King Bio-Medical Inc, Overland Park, Kansas. Plasma depleted in plasma urokinase

was prepared by chromatography on column coupled antibodies to urokinase as described by Kluft et al.[23] Plasma depleted in plasminogen was prepared by chromatography on lysine-agarose (cf ref. 17); the depleted plasma showed no response on immunochemical assay for plasminogen (detection limit about 5%) and a residual activity of 1.6% in the streptokinase method of Friberger et al.[24]

Assays. Modified crossed immunoelectrophoresis with added lys-plasminogen was carried out as described by Kluft and Los.[16] Briefly, the 1% agarose gel for the first dimension in 0.03 mol/L buffer, pH 8.6, contained 1,000 KIU/mL Trasylol and 0.04 mg lys-plasminogen/per milliliter added to the agarose solution just before casting the gel. Before electrophoresis, 5 μL of plasma or serum, 2 μL of lys-plasminogen solution (2 mg/mL), and 1 μL of 10,000 KIU/mL Trasylol were sequentially and rapidly introduced into the punched well. The gel for the second dimension contained antiserum against alpha-2-antiplasmin. The immunoprecipitation peak surface at β-mobility represents the concentration of the PB form of alpha-2-antiplasmin, and at α-mobility, that of the NPB form. The antiserum had a comparable titer for both forms of alpha-2-antiplasmin as checked by assay of mixtures of the PB and NPB forms.[25]

The activity assay of alpha-2-antiplasmin, the immediate plasmin inhibition test, was performed as described by Kluft et al[9] and measured 1.00 PB + 0.14 NPB.[25] The PB and NPB concentrations can be calculated separately knowing the ratio PB-NPB from the modified crossed immuno-electrophoresis and the result of the immediate plasmin inhibition test using a standard (pooled plasma) with a known ratio and amount of inhibitor calibrated on active-site titrated plasmin.[26] Alternatively, PB and NPB concentrations can be determined directly by modified crossed immunoelectrophoresis in simultaneous runs with pooled normal plasma with known amounts of PB and NPB.[25]

Alpha-2-antiplasmin determined immunochemically by the technique of Laurell[27] was expressed in percentage of pooled normal plasma (1.07 μmol/L).

Changes in the conversion rate of plasma in vitro of the two forms of alpha-2-antiplasmin were assessed by incubation of the plasmas for 18 days at 37 °C and assay of the pattern of the modified crossed immunoelectrophoresis. Depleted or deficient plasmas were compared with starting plasma or pooled normal plasma. Effects of inhibitors (25 μL added to 250 μL plasma) were compared with buffer controls. The effects of Cls-esterase, granulocyte enzymes, dextran sulphate, and ellagic acid on the antiplasmin activity in the immediate plasmin inhibition test were studied after 15 minutes' incubation at 37 °C in 1:1 mixtures.

Volunteers and patients. Normal volunteers were from the institute. Heterozygotes with congenital alpha-2-antiplasmin deficiency were from a family described by Kluft et al.[9] Patients with advanced liver cirrhosis were in a stable period. The patient receiving local streptokinase for a thrombus was treated with a bolus injection of 5,000 units and a maintenance dose of 5,000 U/h for 24 hours. The dosage was increased to 10,000 U/h until the therapy was stopped after 97 hours. Samples obtained during and shortly after therapy were analyzed in the modified crossed immunoelectrophoresis assay in a special way. To account for the possible presence and interference by plasmin–antiplasmin complexes at β-mobility, an intermediate agarose gel layer containing antiserum against plasminogen[16] was introduced. In some samples, the precaution proved necessary. Three patients from a larger study[28] of patients with chest pain admitted to hospital with a diagnosis of myocardial infarction, later confirmed by electrocardiography and enzyme studies (AMI <48 hours), were further investigated after demonstration of a rise in activity in the immediate plasmin inhibition test.

Six patients with acute lymphocytic leukemia described by Vellenga et al[29] were studied before the start, at the end, and six to ten days after discontinuation of L-asparaginase intravenous therapy. The daily dosage varied from 5,500 to 7,496 U/m². The total duration of the therapy varied from seven to 17 days and resulted in reduction in the immediate plasmin inhibition test to 5% to 30% of normal, reverting to normal again after discontinuation.[29]

Informed consent was obtained.

Cell culture. The established cell line Hep G2 derived from a human liver tumor was obtained from Dr B.B. Knowles (Wistar Institute of Anatomy and Biology, Philadelphia) and is known to produce alpha-2-antiplasmin.[12] The cells were cultured at 37 °C in 25-cm² flasks containing 0.1 to 0.2 mL/cm² (Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% heat-inactivated fetal bovine serum (Flow Laboratories, Irvine, Scotland), penicillin (100 IU/mL), and streptomycin (0.1 mg/mL) under a 5% CO_2/air atmosphere. For the experiments on alpha-2-antiplasmin, cells were grown to a density of 3 mg protein/25 cm². After two washings with DMEM, 2 mL of fresh medium were added to each flask. Media were harvested after one and eight days of incubation at 37 °C. During the incubation of 11 days, 1 mL of fresh medium was supplied on day 8. The media were centrifuged to remove cellular debris and stored at −20 °C. For the purpose of analysis, the medium was ten times concentrated on a Minicon concentrator B 15 (Amicon BV, Oosterhout, The Netherlands).

RESULTS

Steady state. As shown in Fig 1, the ratio PB-NPB is not significantly dependent on the synthesis rate of alpha-2-antiplasmin under steady state conditions, eg, in stable individuals. The data was obtained from apparently normal individuals, from heterozygotes for congenital alpha-2-antiplasmin deficiency with an approximately half normal plasma concentration, and from patients with liver cirrhosis with an apparently impaired synthesis of the inhibitor in a stable period. (It was recently demonstrated that no enhanced catabolism occurs in such patients.[30]) The total amount of alpha-2-antiplasmin (PB + NPB) was determined by Laurell immunoassay. The ratio PB-NPB in this group (Fig 1) was 2.41 ± 0.34 (SD), well in accord with experience in a larger group of 29 apparently healthy volunteers showing 2.33 ± 0.29 (SD).

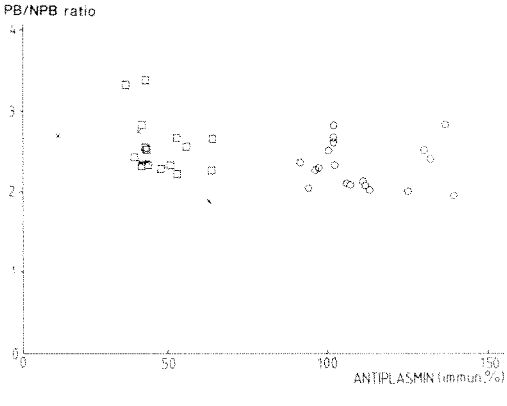

Fig 1. The ratio PB-NPB determined by the modified crossed immunoelectrophoresis technique for healthy volunteers (○; n = 19), patients with a stable liver cirrhosis (×; n = 5), and heterozygotes for congenital alpha-2-antiplasmin deficiency (□; n = 15). The total amount of alpha-2-antiplasmin is determined by the Laurell technique (abscissa).

Acute phase reaction. The alpha-2-antiplasmin activity as well as the PB and NPB forms were determined in three patients who showed an acute-phase reaction after myocardial infarction. During the acute phase, the increase in alpha-2-antiplasmin activity coincided with an increase in PB antiplasmin, while the NPB form remained virtually constant (Fig 2).

Streptokinase therapy. During streptokinase therapy of a patient (see Fig 3), alpha-2-antiplasmin was almost consumed by the active process. After treatment, the alpha-2-antiplasmin activity was restored to almost normal by resynthesis at the first blood sampling (indicated as "3" in the figure). At this particular time, as shown by the modified crossed immunoelectrophoresis pattern, the PB alpha-2-antiplasmin had almost exclusively reappeared.

L-asparaginase therapy. During L-asparaginase therapy, synthesis of alpha-2-antiplasmin was inhibited. A gradual, functional, and immunochemical lowering of the plasma concentration with a half-life of approximately five days was observed in six patients. At the discontinuation of therapy, alpha-2-antiplasmin was found to be 26% ± 9% of normal (immunoassay). A concomitant significant change was observed in the ratio of PB-NPB for all patients: from 2.86 ± 0.55 at the start to 1.74 ± 0.24 at the end of treatment. This indicates a selective reduction in PB alpha-2-antiplasmin. After treatment, resynthesis resulted in recovery of normal alpha-2-antiplasmin levels (92% ± 12%, after about eight days) and an increased PB-NPB ratio of 4.65 ± 1.32 (n = 6), indicating selective increases in PB alpha-2-antiplasmin.

Hep G2 cell culture. The hepatoma cell line Hep G2 produces alpha-2-antiplasmin[12] linearly in increasing amounts, with the incubation time as shown in Fig 4 by normal crossed immunoelectrophoresis. In the modified crossed immunoelectrophoresis, significant amounts of PB alpha-2-antiplasmin only were present at day 1, while on day 11 the NPB form had also appeared.

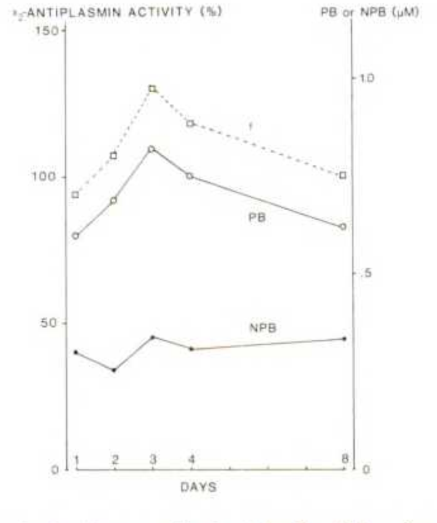

Fig 2. Acute-phase reaction in alpha-2-antiplasmin activity (f) in three patients with acute myocardial infarction. The PB and NPB forms are calculated from data from the modified crossed immunoelectrophoresis technique (PB-NPB ratio) and the activity assay (PB + 0.14 NPB) and expressed in μmol/L by comparison with normal plasma determined to contain 1.07 μmol/L alpha-2-antiplasmin in a PB-NPB ratio of 2.2.[25] The activity is determined by the immediate plasmin inhibition test and expressed in percentage of pooled normal plasma. The samples are collected at the indicated days after admission of the patient to hospital.

Incubations in vitro. Incubation of citrated pooled normal plasma in vitro was found to result in a slow decay of alpha-2-antiplasmin activity. Figure 5 shows that this pro-

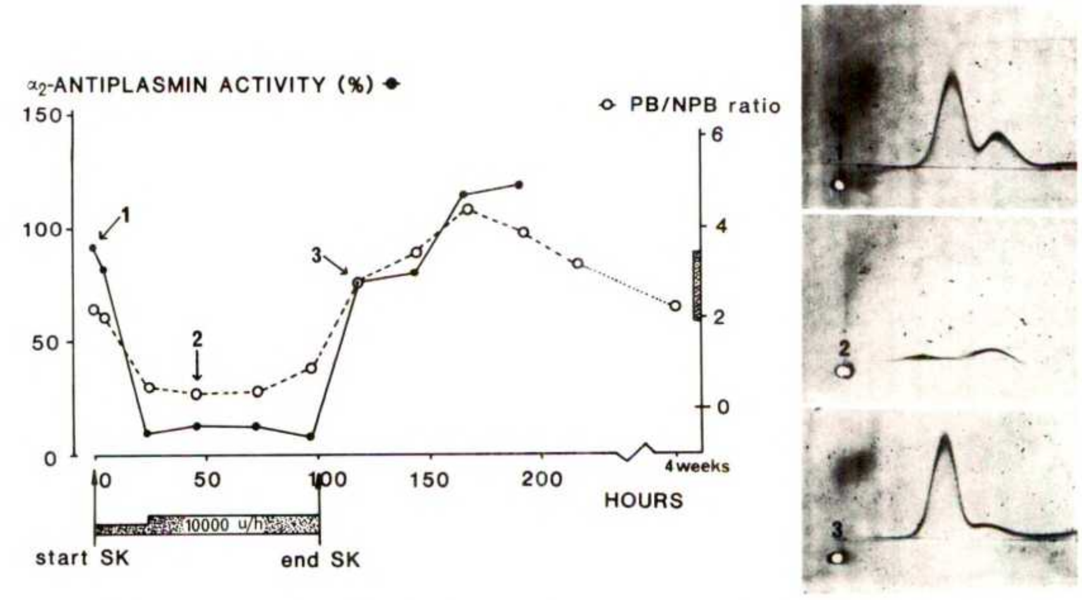

Fig 3. The two forms of alpha-2-antiplasmin during and after streptokinase therapy. The activity of alpha-2-antiplasmin is recorded by means of the immediate plasmin inhibition test and recorded in percentage of pooled normal plasma (ordinate). The PB-NPB ratio is determined by the modified crossed immunoelectrophoresis technique (normal range is indicated) and the gels for the indicated points 1, 2, and 3 are given in the insert.

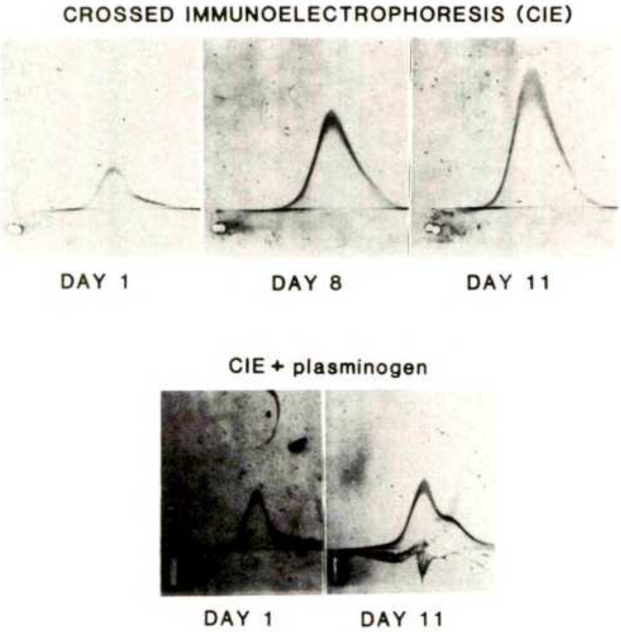

Fig 4. Production of alpha-2-antiplasmin in culture media of Hep G2 cells. Normal crossed immunoelectrophoresis shows an increased production with time (upper panel). Modified crossed immunoelectrophoresis (CIE + plasminogen) of medium (concentrated to comparable alpha-2-antiplasmin concentrations) of day 1 and day 11 are given in the lower panel.

cess exhibits individual variation that, for the initial rate, was estimated to show a range of ± 20% around the mean. As shown in Fig 6 for pooled normal plasma, the process is moderately temperature dependent, with an increase in rate of a factor of 2.4 and 1.9 for 0 °C to 25 °C and 25 °C to 37 °C, respectively.

As shown in the insert of Fig 6, the decay of activity is accompanied by a conversion from PB to NPB alpha-2-antiplasmin. Combining the activity assay and the modified crossed immunoelectrophoresis to determine PB and NPB separately (see Materials and Methods), it was demonstrated (as shown for pooled normal plasma in Fig 7) that the PB form shows a first-order decay with a half-life of eight days.

The conversion of PB to NPB on in vitro incubations was found to be uninfluenced by a number of circumstances. The

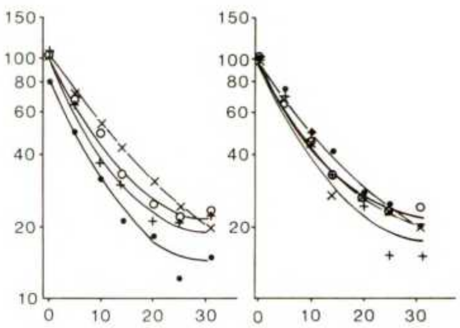

Fig 5. Decay of activity in the immediate plasmin inhibition test by incubation of citrated plasma (with azide) of eight apparently healthy volunteers for the indicated periods (abscissa) at 37 °C. The results of the inhibition assay are recorded in percentage of that of pooled plasma (ordinate, log scale). The activity decay shows the conversion of PB to NPB because of the reduced expression of NPB relative to PB (14%; ref. 25) in the activity assay.

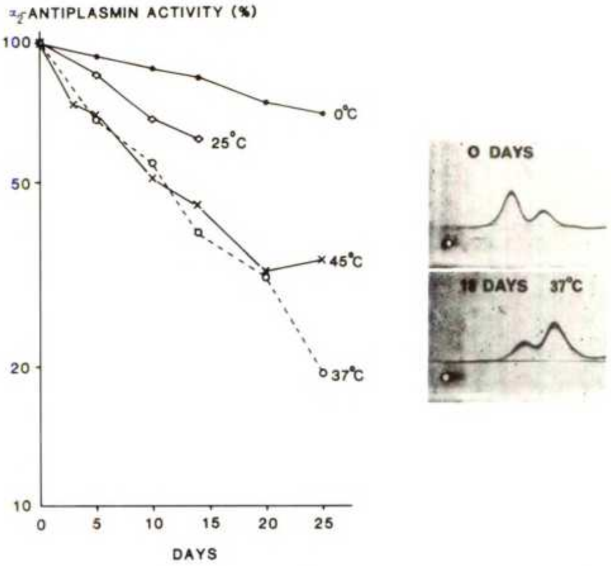

Fig 6. Decay of alpha-2-antiplasmin activity determined by the immediate plasmin inhibition assay (expressed in percentage of pooled plasma, ordinate, log scale) after incubation of citrated pooled plasma (with addition of azide) at various temperatures. The insert shows a typical example of the change from the PB to the NPB form during the incubation. (The exhibit gels are not run under identical conditions for the first dimension.)

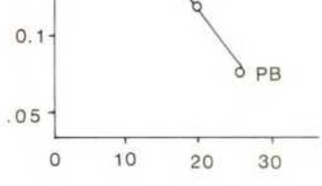

Fig 7. The conversion of PB to NPB in citrated pooled plasma by incubation at 37 °C for the indicated periods (abscissa). PB and NPB (log scale) are calculated from the following data from each sample: modified crossed immunoelectrophoresis gives PB/NPB; the immediate plasmin inhibition test gives PB + 0.14 NPB. Results were in accord with direct assay of PB in one run of the modified crossed immunoelectrophoresis for t = 0, 12, and 20 days.

conversion was no different in normal serum or plasma deficient in factor XII or factor XIII, or in plasma depleted in plasminogen (by sepharose-lysine[17]) or plasma urokinase (by immunoadsorption[23]). The conversion was not influenced by EDTA (1 mmol/L), by addition of granulocyte enzymes, by contact activation by either ellagic acid (1:1 with 10^{-4} mol/L) or dextran sulphate (1:1 with 25 μg/mL), or by addition of Cls-esterase (375 U/mL). The addition of the following inhibitors (highest final concentrations tested) did not prevent the conversion, as judged from the conversion after 18 days in the modified crossed immunoelectrophoresis: DFP (1 mmol/L), soya bean trypsin inhibitor (100 μg/mL), Trasylol (100 KIU/mL), benzamidine (100 μg/mL), lima bean trypsin inhibitor (100 μg/mL) ovomucoid (20 μg/mL), ovoinhibitor (100 μg/mL), elastatinal (1 μg/mL), pepstatin (1 μg/mL), chymostatin (1 μg/mL), iodoacetamide (100 mmol/L), β-mercaptoethanol (0.1 mmol/L), $HgCl_2$ (1 mmol/L), and $ZnCl_2$ (1 mmol/L).

DISCUSSION

Using modified crossed immunoelectrophoresis, the two forms of alpha-2-antiplasmin, PB and NPB, could be separately determined and both were present in all plasmas studied. The ratio between the forms was found to be rather constant among individuals, with a mean molar ratio of PB-NPB of 2:41. This was irrespective of the largely variable synthesis rate of alpha-2-antiplasmin, which resulted in corresponding plasma levels of total alpha-2-antiplasmin of 16% to 138% obtained by studying patients with stable liver cirrhosis, heterozygotes for alpha-2-antiplasmin, and normal individuals.

In situations where synthesis of new or additional alpha-2-antiplasmin was observed, such as after depletion by streptokinase or L-asparaginase therapy, or in acute-phase conditions after myocardial infarction, primarily the PB form of alpha-2-antiplasmin was found to be produced. Accordingly, in cultures of the hepatoma cell line Hep G2, the PB form was found to be initially produced, and only later was the NBP form also detected in the culture media. This demonstrates that the liver produces primarily (probably exclusively) the PB form of alpha-2-antiplasmin. As to the origin of the NPB forms of alpha-2-antiplasmin, it was demonstrated that the PB form apparently spontaneously converts to the NPB form in vitro. This was demonstrated in platelet-poor citrated plasma and indicates the involvement of plasma components; alternatively, the conversion involves an intrinsic property of alpha-2-antiplasmin. Assuming the exclusive synthesis of the PB form, the occurrence of the NPB form in vivo is evidence for its formation there as well. In addition, the data showing a more rapid disappearance of the PB form relative to the NPB form (decrease in the PB-NPB ratio) during therapy with L-asparaginase is compatible with and explained by an in vivo conversion of PB to NPB.

The data on conversion in vitro and the in vivo data agree when related to each other in a minimum hypothesis, which is also based on published data, as shown in Fig 8. First-order reactions are proposed for catabolism ($k2$, $k3$) of both forms and, as demonstrated in Fig 8, for the conversion of PB to NPB ($k1$). The recognition of the PB-NPB conversion implies that previous studies on the catabolism of injected radiolabeled alpha-2-antiplasmin do not report exclusively on $k2$. In the proposed model, the plasma half-life is represented by $\ln 2/(k2 + k3k1)$. This has been determined by Collen and Wiman[31] to give a half-life of 2.83 days on injecting healthy subjects with a preparation that, according to our evaluation of a similar one, mainly represents the PB form ($\geq$95%) (courtesy of Drs Knot and Collen; see ref.[30]). Using the additional information that the mean PB-NPB ratio in healthy subjects is 2.33, which represents $k3/k1$ during steady state, we can conclude that $k2$ in this model actually corresponds to a half-life of three days. In the model, then, $k1$ and $k3$ remain undetermined for the in vivo situation. If we assume the in vitro conversion of PB to NPB to be representative for the in vivo process, we can calculate that $k3$ has a value corresponding to a half-life of 3.4 days. These values are similar to the half-life of the plasma alpha-2-antiplasmin of 3.3 days, determined by Tamaki et al[32] by infusion of normal fresh plasma (PB + NPB mixture) in a patient with congenital deficiency of alpha-2-antiplasmin. It is not unrealistic to assume that both alpha-2-antiplasmin forms have closely similar catabolic rates, but definite proof awaits a direct determination of the catabolism of the NPB form. Alternatively, the assumption that the catabolic rates of both forms are identical results in a calculated $k1$ for the in vivo conversion comparable to a half-life of 7.2 days, which is close to the in vitro value of eight days.

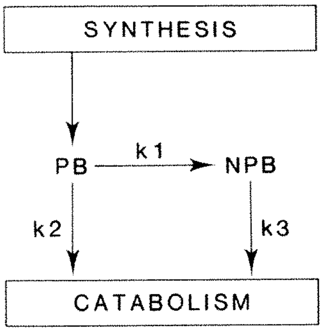

Fig 8. Proposed model for the mutual relationship between the PB and NPB forms of alpha-2-antiplasmin in the circulation. *k1*, *k2*, and *k3* represent first-order rate constants.

It is concluded that the model describes the quantitative aspects of the relationship between the two forms and implies no present need to assume other processes than the ones observed in vitro to describe the mutual relationsip between the two forms of alpha-2-antiplasmin. Further considerations are:

1. In the proposed model, the ratio PB-NPB is independent of the synthesis rate of alpha-2-antiplasmin in a steady state, as actually observed (Fig 1).
2. When synthesis is blocked, a relatively rapid decrease in the PB form in relation to the NPB form occurs, resulting in a shift in the PB-NPB ratio, as actually observed during asparaginase therapy.
3. The individual variation in the PB-NPB ratio (Fig 1) can only originate in a variation in $k1$, $k2$, or $k3$. According

to the data in Fig 6, it can originate in the variation in $k1$, which shows a comparable variability to that of the PB-NPB ratio.

The nature of the conversion process is not elucidated by this study, but it has been demonstrated that it concerns a temperature-dependent process in vitro, with a more moderate temperature dependence than enzymatic reactions ($Q_{10} = 2$ to 4). The recent report of Sasaki et al[33] that a C-terminal peptide has plasminogen-binding properties (cf ref. 34) would suggest the possibility of splitting off such a peptide. Our attempts to inhibit the conversion by a spectrum of protease inhibitors (directed to various serine and thiol proteases) was unsuccessful, and a number of proteases tested (added or generated in the plasma) were incapable of achieving or enhancing the conversion. It is significant that our experiments practically exclude the involvement of the known hemostasis components: fibrinogen, fibrin, factor XIII, plasminogen, plasma prourokinase, factor XII and its related processes. This strongly suggests the involvement of a previously unknown component or of an intrinsic property of the alpha-2-antiplasmin; the latter may be relatively less likely in view of the individual variation in the conversion (Fig 5).

The significance of the conversion of PB to NPB alpha-2-antiplasmin and that of the NPB form has still to be established. It appears that the NPB form represents partial inactivation of the alpha-2-antiplasmin as it is a much less reactive inhibitor with a substantially less avid plasmin inhibition and does not participate in plasminogen binding and not significantly in binding by the fibrin stabilizing factor (factor XIII) to fibrin. One of the important mechanisms to direct fibrinolytic processes or actions of plasminogen activators to fibrin lies in the particular features of the PB form of alpha-2-antiplasmin.

Because of the low spontaneous velocity of the conversion process, the conversion can only be involved in slow processes. This might be the case in setting free fibrinolysis in aging thrombi, in cavities with a slow flow, such as the synovium or cystes, and in parts of the extracellular space; however, the conversion may be enhanced, possibly locally.

Discovery of the mechanism, or hypothetical factors or cofactors, in the conversion process and manipulation of the conversion by these or related components might present an intriguing possibility for fibrinolytic therapy and might help to establish the importance of the process, especially if it proves to be liable to local variation.

Iron Metabolism in the Belgrade Rat

By John Edwards, Helmut Huebers, Christoph Kunzler, and Clement Finch

Iron metabolism in the Belgrade rat was examined in the intact animal and in the reticulocyte suspensions. The plasma iron turnover was increased. However, when allowance was made for the effect of the elevated plasma iron concentration, erythroid marrow capacity for iron uptake was at basal levels. Numbers of erythroid cells in marrow and spleen measured by the radioiron dilution technique were increased. Thus iron uptake was not proportionate to the erythroid hyperplasia in the b/b rat, despite a more than adequate plasma iron supply. This relative deficiency in iron uptake was reflected in a severe microcytosis and elevated red cell protoporphyrin.

Reticulocyte incubation studies demonstrated an unimpaired uptake of the transferrin–iron–receptor complex but a marked reduction in iron accumulation. The diferric transferrin molecule, when it did give up iron within the cell, released both of its iron atoms so that only apotransferrin was returned to the media. In contrast to the nearly complete release of iron within the normal reticulocyte, the major portion of iron taken up by the Belgrade reticulocyte was returned to the plasma. The release mechanism that can be impaired in iron-deficient reticulocytes by EDTA or cadmium was shown to be affected by lower concentrations of these substances in the Belgrade reticulocyte. It is concluded that the Belgrade rat has an abnormality of iron release within the absorptive vacuole that is responsible for a state of intracellular iron deficiency, involving the erythron and other body tissues.

© 1986 by Grune & Stratton, Inc.

THE ANEMIA of the Belgrade rat is an autosomal recessive trait, determined by a radiation-induced mutation.[1] It is characterized morphologically by red cell hypochromia, microcytosis, and reticulocytosis.[2] There is a modest increase in total iron-binding capacity of the serum with a proportionately greater increase in the serum iron concentration.[2] Despite the hyperferremia, however, there is an absence of stainable iron in the body tissues and a lack of sideroblasts in the marrow.[2] Studies in a small number of animals suggest that iron utilization for hemoglobin synthesis is reduced.[3] Parenteral iron treatment fails to cure the anemia, even though it results in a gross iron overload of spleen and liver [2]

More detailed studies of the behavior of immature erythroid cells have shown an impaired iron uptake of transferrin iron.[4] Globin chain synthesis in reticulocytes, as measured by the incorporation of 3H-L-leucine in vitro, is decreased but balanced.[4] Incubation of reticulocytes with exogenous hemin partially corrects the defect in globin synthesis but has little effect on iron uptake.[5] When reticulocytes are exposed to ^{59}Fe, ^{125}I-labeled transferrin, there is an unimpaired uptake of transferrin but a decreased uptake of iron.[6,7] The examination of ^{125}I-labeled cell membrane in acrylamide gel does not disclose an obvious difference in receptor sites for transferrin.[7] In summary, past studies have shown a block in the acquisition of iron by body tissues, the nature of which has not been precisely defined. The purpose of this study was to provide more quantitative dimensions to the iron uptake abnormality and to define the nature of the abnormality.

MATERIALS AND METHODS

Anemic Belgrade laboratory male rats (b/b) of a mixed genetic background were mated with normal female Long Evans rats to provide obligatory heterozygotes. These heterozygotes were intercrossed to provide anemic (b/b) and nonanemic (−/b, −/−) control animals for studies of erythropoiesis. Because it was not possible to distinguish between −/b carriers and −/− normal homozygotes, the expression −/? will be used to denote the nonanemic control animals. Although heterozygous (+/b) litter mates are not normal from the genotypic point of view, they are normal phenotypically Other workers and ourselves have not been able to demonstrate any phenotypic differences between +/+ and +/b animals In view of the high reticulocyte count of b/b animals, normal animals rendered iron deficient by bleeding and low iron diet with comparable reticulocyte counts were used in incubation studies as a control.

Ferrokinetic studies. Plasma iron turnover measurements were performed by injecting radioiron as $FeSO_4$ intravenously into control animals and radioiron bound to normal plasma into homozygous animals [8] In the latter instance, the iron saturation of transferrin was set at that present in vivo, usually about 80%. Five samples of blood, each 0.2 mL, were withdrawn from the tail vein over the anticipated T½ disappearance time, and additional blood was drawn with the last sample for determination of plasma iron concentration and total iron-binding capacity. The plasma iron turnover (mg of iron/dL whole blood/d) was calculated according to the formula:

$$\frac{\text{PIT} = \text{plasma iron } (\mu/\text{dL}) \times \text{plasmatocrit}}{\text{T}^{1\!/\!2}\,(\text{min}) \times 100}.$$

In addition, a correction was made for the effect of plasma iron concentration on plasma iron turnover.[9] In this correction, the PIT is converted to that which would be found at 100% transferrin saturation. The basis for this correction is the molecular advantage of 11.6 in iron delivery by diferric transferrin as compared with monoferric transferrin in the rat. The formula is:

$$\text{PIT at 100\% sat} = \text{PIT(s)} \times \frac{\frac{200}{s} + 9.6}{11.6},$$

where s = transferrin iron saturation

Erythroid cell number. Total marrow cellularity was determined in rats sacrificed six to eight hours after the injection of radioiron at which time plasma activity had decreased to <20% of the original level. Animals were exsanguinated and perfused with saline. Total marrow cellularity was determined in these animals by relating the cell count and radioactivity of an aliquot of marrow to the radioactivity of the total skeleton as previously described.[10] Immediately after death, one humerus was removed and its activity was determined. Then its marrow was flushed from the open end, using a syringe filled with Hanks' buffered saline solution. The collected cells were refluxed with a syringe and 27-gauge needle until a uniform cell suspension was obtained. The number of cells and radioactivity of this suspension was determined. Then the suspension was centrifuged at 400 g and the supernate removed for determination of radioactivity. The animal carcass minus the viscera was then autoclaved and all bones removed for determination of total skeletal activity.

Marrow cellularity (MC) was determined in two ways. The first method calculated total erythroid cells of the marrow from the number of erythroid cells counted in the aliquot and the total activity of the aliquot (cells and supernate) as compared with skeletal activity. The second method calculated total erythroid marrow cellularity from the number of erythroid cells in the aliquot and the radioactivity of centrifuged cells alone *v* that of the total skeleton. If activity in the supernate of the aliquot represented shed cytoplasm but the cells were still countable, the first method would be the appropriate one. If the activity in the supernate of the aliquot represented broken cells that could not be counted, the second method would be proper. These two calculations are assumed to represent minimum and maximum figures, the true value lying somewhere between. The formulas used for these two calculations were as follows:

$$\text{MC (minimal)} = \text{aliquot erythroid cells} \times \frac{\text{total skeletal activity}}{\text{total cell suspension activity}}$$

$$\text{MC (maximal)} = \text{aliquot erythroid cells} \times \frac{\text{total skeletal activity}}{\text{aliquot cell button activity}}$$

In addition, at the time the animal was killed, the spleen was removed and weighed and activity was determined. An aliquot of spleen was then weighed and torn apart so as to release its cell content into Hanks' solution. This cell suspension was centrifuged, the supernate removed, and plasma substituted. It was then diluted to a known volume and shaken to a uniform suspension, and cells were counted. By relating the aliquot to the total spleen through weight ratio, total cell count was calculated.

$$\text{Splenic erythroid cells} = \text{splenic aliquot erythroid cells} \times \frac{\text{splenic weight}}{\text{aliquot weight}}.$$

Reticulocyte assay. Reticulocyte-rich blood (reticulocyte count 28% to 38%) was obtained from Belgrade and genetically normal iron-deficient rats. The cells were washed and preincubated in Hanks' balanced salt solution for 15 minutes to deplete the cells of prebound transferrin.[9] Then cells were incubated in Hanks' buffer with the transferrin preparations labeled with ^{55}Fe and ^{125}I or ^{59}Fe and ^{55}Fe (see Results) in Hanks' buffer. In chaser experiments, the cells were incubated for ten minutes at 37 °C with the tagged transferrin and 11 μg of cold diferric transferrin iron was added to start the chase. Populations of blood cells from iron-deficient control rats and Belgrade rats with the same reticulocyte count (28% to 33%) were prepared. Otherwise, the incubation mixture consisted of a transferrin concentration 1.0 mg/mL, dissolved in Hanks' balanced salt solution, pH 7.4, hematocrit 20% to 25%. A typical total volume for a single uptake evaluation was 0.72 ml.

Transferrin preparation. Purification and iodination of rat diferic transferrin with ^{125}I were done as described elsewhere.[11] Transferrin was converted to apotransferrin by using desferrioxamine.[12] For the preparation of di [^{59}Fe] ferric transferrin, 30 μCi of ^{59}Fe (13 to 22 μCi/μg of iron, dissolved in 0.5 mol/L HCl) (1 Ci = 3.7 × 10^6 Bq), was added to 50 mg of ^{125}I-labeled apotransferrin (100 μCi of ^{125}I) dissolved in 5 mL of 0.05 mol/L Tris HCl, pH 8.0/0.01 mol/L $NaHCO_2$. This was followed by the addition of sufficient iron as ferrous ammonium sulfate (273 μg of iron per milliliter in 0.01 mol/L HCl) to saturate exactly the free iron-binding sites present in the transferrin solution. This was achieved by a spectrophotometric titration technique in which the increase in color development at = 465 nm was observed.[12] At the point of saturation, the A465-A280 ratio of the transferrin solution was 0.046, characteristic of the diferric state of the transferrin molecule.[11] Monoferric transferrin was prepared by column chromatography on Sephadex G50 at pH 5.1. Double-labeling of the purified transferrin was achieved by first labeling all sites with ^{59}Fe, removing the iron from the acid labile site by chromatography at pH 5.1, and then saturating the open sites with $^{55}FeSO_4$.[11] The preparation had a specificity of site binding of more than 80%. No site-to-site exchange of isotope occurred when stored at 4 °C in 1 mmol/L bicarbonate-buffered saline (pH 7.4) for at least three weeks, as shown by repeating the Sephadex G-50 separation.[8] In addition, the incubation of the selectively labeled diferric transferrin preparation in Hanks' buffer at 37 °C for two hours without or with washed reticulocytes failed to show any scrambling of the two isotopes.

Miscellaneous methods. Hemoglobin was determined by the cyanmethemoglobin method, hematocrit by the micromethod, and red cell count was done manually. Plasma iron and iron-binding capacity were determined according to standard methods. Red cell protoporphyrin was determined spectrophotometrically.[13] Nonheme iron analyses were carried out by wet ashing and colormetric analysis, as described in Bothwell et al.[14] ^{59}Fe was counted in a gamma counter, whereas samples for ^{55}Fe analysis were wet ashed and counted in a scintillation counter.[15] When ^{59}Fe along with ^{125}I were used, both isotopes were measured without extraction in an autogamma scintillation spectrometer (Packard, Model 5330). Simultaneous measurement of ^{59}Fe and ^{55}Fe activity was carried out after acid digestion, using the method of Eakins and Brown, in a liquid scintillation counter (Packard, Model 2405).[15] Isolectric focusing in polyacrylamide gel was carried out as described elsewhere.[11] The methods of incubation, washing, wet ashing of the cells, counting radioactivity, chemical iron determination, and statistical evaluation were the same as previously described by this laboratory.[8,11,12] Variations are expressed as ± 1 SD.

Reagents for in vitro studies. Ferrous ammonium sulfate [$(NH_4)\ Fe(SO_4) \times 6H_2O$] was purchased from Baker Chemical Co, Phillipsburg, NY. Disodium EDTA and cadmium chloride ($Cd\ Cl_2 \times 2\frac{1}{2}\ H_2O$) were obtained from Sigma Chemical Co, St Louis, and from Analar BDH Chemicals Ltd, Poole, England, respectively. A 0.1 mol/L EDTA stock solution in saline was prepared and adjusted to pH 7.4 by the addition of 0.1 mol/L HCl. A 0.115 mol/L Cd CL_2 stock solution in pH 2.0 saline was prepared and stored at this low pH and neutralized in the experimental mixture by the addition of 0.5 mol/L HEPES buffer (pH 7.4).

RESULTS

Studies of erythropoiesis. Hematologic data on four adult homozygous (b/b) animals and four adult control litter mates, either heterozygous or normal (−/?), reared under

identical conditions were determined. Their respective mean hemoglobin concentration was 7.5 and 11.8 g/dL, mean cell volumes 34 and 63.4, and mean corpuscular hemoglobin concentration 19.0 and 27.8. Thus each b/b red cell had 0.37 the amount of hemoglobin as compared with the –/? red cell. Protoporphyrin values on four homozygotes were elevated to a mean value of 176 ± 74 as compared with a control value of 28 ± 6 μg/dL RBC. Liver and spleen iron content was lower in b/b animals than in controls, ie, 2.6 ± 2.0 *v* 5.5 ± 1.4 mg of iron. Despite this evidence of iron deficiency in circulating red cells and other tissues, plasma iron and transferrin saturation of the b/b animals (Table 1) were elevated significantly above those of control animals.

Quantitative measurements of erythroid cellularity (Table 1) showed an increase of between two and three times controls in the nucleated red cell precursors within the skeleton and a still greater increase in nucleated cells in the enlarged spleen of the homozygous rats. The total number of erythroid cells (spleen and marrow) of b/b animals was increased to about four times that of –/? rats. While the two methods of calculating total erythroid precurser cellularity gave different values, the comparison between homozygote b/b and –/? was almost identical, ie, 4.2 *v* 4.1 × basal.

The plasma iron turnover of homozygous animals averaged 2.5 mg/dL per whole blood per day as compared with 2.0 mg in control animals. However, if a correction was made for the effect of the higher plasma iron concentration in the homozygous animals,[9] the calculated plasma iron turnover of the two groups of animals at a transferrin saturation of 100% showed essentially no difference, ie, 2.6 and 2.5 mg iron per deciliter of whole blood. Thus, despite a far greater number of red cell precursors, a better iron supply, and a lower hemoglobin, the homozygous animals showed no increase in erythroid iron uptake. Red cell utilization of radioiron was similar in the two groups, ie, 81 ± 11 in the b/b *v* 86 ± 7 in the –/? animals.

Reticulocyte iron uptake and release. Further studies were directed more specifically at the defective reticulocyte

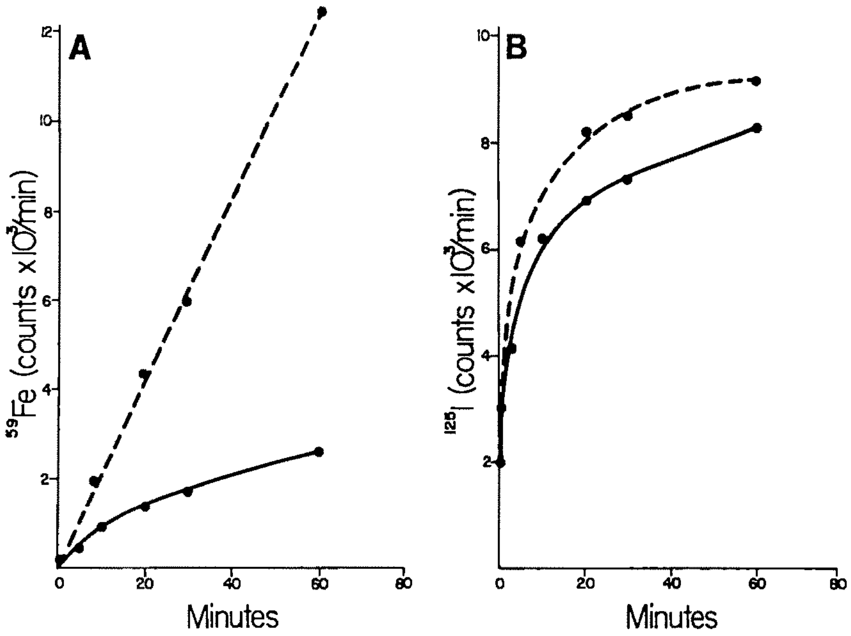

Fig 1. Uptake radioiron and ^{125}I-labeled transferrin by b/b reticulocytes (solid line) and iron-deficient reticulocytes (dashed line). Belgrade reticulocytes accumulated far less iron (a), whereas transferrin uptake appeared similar (b).

iron uptake (Fig 1). When reticulocytes from the b/b and reticulocytes from iron-deficient genotypically normal rats were incubated with iron-saturated ^{59}Fe- and ^{125}I-labeled transferrin (2 mg/mL at 37 °C), radioiron uptake was similar only during the first few minutes of incubation, and by 60 minutes, the uptake by b/b reticulocytes amounted to about one fourth that of the iron-deficient control reticulocytes. This occurred despite a similar initial ^{125}I transferrin uptake.

Iron release in the normal reticulocyte is known to involve complete removal of iron from transferrin. This aspect was examined by using a doubly-labeled rat transferrin carrying ^{55}Fe on the acid stable site and ^{59}Fe at the acid labile binding site. At incubation, the normalized uptake ratio (determined by the ^{55}Fe-^{59}Fe uptake in the reticulocyte divided by the ^{55}Fe-^{59}Fe ratio in the media) was 1.0 ± 0 01 (n = 5) for the Belgrade rat and 0.99 ± 0.01 (n = 5) for the iron-deficient control reticulocytes. There could still be a random removal of one iron from the two sites, resulting in exiting of monoferric transferrin from cells. To investigate this, ^{59}Fe-tagged diferric transferrin was used in which the protein part of transferrin was labeled with ^{125}I. After a 60-minute incubation, during which about 60% of the radioiron was removed by the iron-deficient reticulocytes and 16% by the Belgrade reticulocytes, isoelectric focusing profiles were prepared on the media (Fig 2). No accumulation of monoferric transferrin was seen in either and the amount of apotransferrin was proportional to the iron uptake by reticulocytes in the two cell mixtures.

That the abnormality involved the iron release mechanism was shown by a chase study (Fig 3). After ten minutes of preincubation of reticulocytes at 37 °C with diferric ^{55}Fe, ^{125}I rat transferrin, a 20-fold excess of nonradioactive diferric rat transferrin was added and the incubation continued for another 20 minutes. A rapid efflux of ^{125}I out of the cells was observed, essentially the same with Belgrade and iron-deficient reticulocytes. On the other hand, the behavior of ^{59}Fe was quite different (Fig 3B). No efflux of ^{59}Fe from control reticulocytes was observed, while Belgrade reticulocytes lost about 70% of the ^{59}Fe taken up during the preincubation period

This abnormal iron release became more evident when reticulocytes were exposed to EDTA or cadmium (Fig 4). Both of these inhibitors reduced iron accumulation in cells when present in millimolar concentration The effect on Belgrade reticulocytes, however, was much greater than on control reticulocytes from iron-deficient animals. No effect on iron delivery was observed when the cadmium EDTA complex (1 mmol/L Cd^{2+}, 2 mmol/L EDTA) was incubated with reticulocytes of either experimental animal (data not shown).

DISCUSSION

Belgrade rats have an autosomal recessive trait that, in its homozygous form (b/b), leads to a microcytic hypochromic anemia [2] While erythroid cells have the features of iron deficiency, including a decrease in hemoglobin content and elevated red cell protoporphyrin, some features are quite different from those expected in iron deficiency. Most conspicuous is the ample plasma iron, whereas body tissues are iron depleted. These findings suggest an iron block involving both gastrointestinal absorption and iron uptake from transferrin by body tissues. Of interest is the demonstration that the block in erythroid uptake does not appear to interfere with erythroid proliferation but does interfere with hemoglobin synthesis. Measurements by the authors on iron-deficient animals with severe anemia (mean hematocrit 15) show a total erythroid cellularity of 7 1 × 10^9/kg as compared with the mildly anemic homozygous Belgrade rats, with an erythroid cellularity of 18 × 10^9/kg. This implies that the Belgrade defect is less limited in the early phase of red cell development involving stem cell proliferation as compared with the late stages, in wich hemoglobin synthesis predominates.

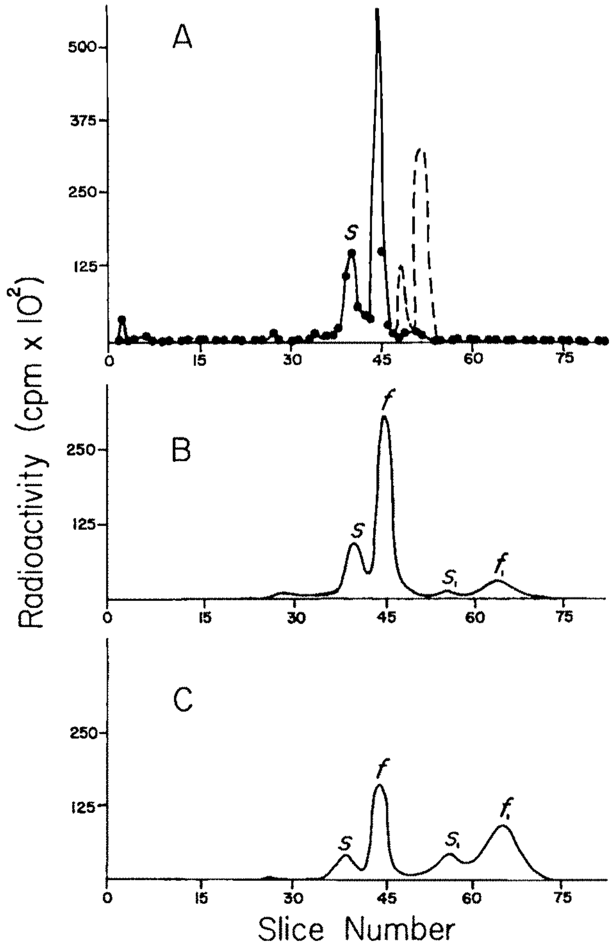

Fig 2. Chromatographic profile of ^{125}I-labeled transferrin. (A) Isoelectric focusing profile of the two diferric rat transferrins before exposure to reticulocytes. Superimposed in a dotted line is shown the locations of the two monoferric forms of rat transferrin. (B) Profile of transferrin after its incubation with b/b reticulocytes. (C) Similar profile after exposure to iron-deficient reticulocytes. Both (B) and (C) show the two peaks of slow and fast rat apotransferrin, the greater amount in (C) corresponding to the greater iron uptake by the iron-deficient reticulocytes. In neither were peaks of monoferric transferrin seen.

The extremely high plasma iron and transferrin saturation

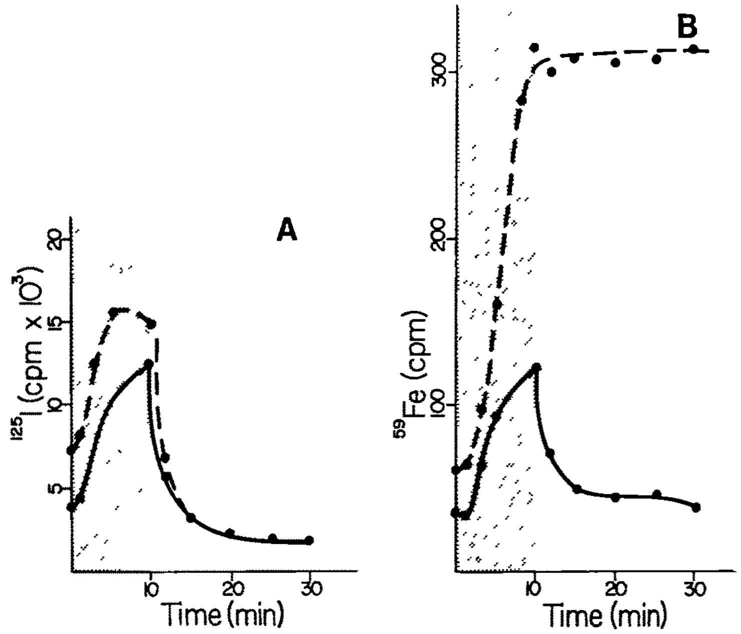

Fig 3. A chase experiment in which there was a preliminary incubation of reticulocytes with transferrin labeled both with radioiron and ^{125}I for a period of ten minutes. Thereafter, a large amount of nonradioactive diferric rat transferrin (7.9 mg containing 11 µg iron) was added to the mixture. Uptake by b/b reticulocytes is shown by solid line and that of iron-deficient reticulocytes is shown by dotted line. In the diagram on the left, the similar rate of release of transferrin from the reticulocyte mixture is seen. In the diagram on the right, a rapid release of iron is observed from b/b reticulocytes but not from normal reticulocytes.

suggest an activation of the iron procurement mechanism within the body. It has been shown that increasing the number of immature erythroid cells somehow results in an increased procurement of iron.[16] In thalassemia, the effect of erythroid proliferation is to increase absorption and total body iron, leading to parenchymal iron overload. In these animals, it would appear that total body iron cannot be increased because of an absorptive abnormality, but that the gradient between iron-donating tissues and plasma iron is altered so as to increase plasma iron supply. Because the delivery of iron to the erythron is not increased, procurement cannot be simply a replacement of iron after its removal from transferrin as previously suggested, but to some other aspect of erythroid hyperplasia.[17]

Previous studies have shown a marked shortening in red cell life span by the chromium-51 technique to seven days in b/b animals as compared with 19 days in controls.[2] These studies, however, were done with younger animals that show a severer degree of anemia. In the present study, while the number of b/b red cell precursors was about four times normal, this would represent a hemoglobin production of only 1.3 times basal, since red cells contained only about one third the hemoglobin concentration of −/? red cells. The basal turnover of plasma iron gives no indication of hemolysis and suggests, if anything, that part of the increase in erythroid cellularity in these animals might be due to a lengthened maturation time. Splenomegaly was accounted for by the marked increase in erythropoiesis within the spleen

Attention then focuses on the series of events occurring when the iron is taken up by the red cell. If there were defective unloading of iron from transferrin, this would not be seen by ferrokinetic techniques, since the shunt in and out of the red cell occurs so rapidly. The currently accepted model for transferrin-mediated delivery of iron to the mammalian erythroid cell involves a number of steps.[18] Diferric or monoferric transferrin binds to a receptor on the plasma membrane at neutral pH, and the complex is endocytosed into the cell cytoplasm. The endocytotic vesicle would be expected to contain an adenosine triphosphate-dependent proton pump, which acidifies its contents. Iron is released from transferrin in the acid environment of the vesicle and somehow transported across its membrane into the cytoplasm and ultimately to the mitochondria for incorporation into heme. The apotransferrin–receptor complex returns to the surface of the cell and fuses with the plasma membrane. On exposure to a higher pH, apotransferrin leaves the receptor and becomes available for reutilization.[19]

In the Belgrade rat reticulocyte, the initial steps involving transferrin–receptor interaction and transferrin–iron–recep-

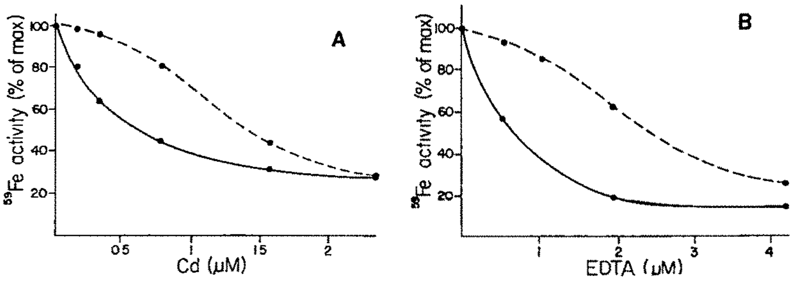

Fig 4. The effect of EDTA and cadmium on radioiron uptake by b/b (solid line) and iron-deficient (dotted line) reticulocytes. Uptake is presented as a percentage of uptake in the absence of these substances. Effects of EDTA are shown in the lower diagram and of cadmium ions in the upper diagram. With both substances, the degree of suppression of iron uptake is much greater with b/b reticulocytes.

tor internalization are intact. However, the release of iron from transferrin in the cell interior is greatly diminished. The release mechanism, although quantitatively abnormal, appears to be qualitatively normal, because when iron is removed from the cell, only apotransferrin is returned to the medium.

The release of iron from transferrin within the genotypically normal iron-deficient reticulocyte is impaired by EDTA and cadmium ions. In this regard, Belgrade reticulocytes are much more sensitive than normal reticulocytes to the effect of EDTA and cadmium ions. Because EDTA can chelate calcium and magnesium, and because cadmium, due to its chemical similarity, can compete with calcium and magnesium, it is possible that the molecular lesion in the Belgrade rat involves a calcium-dependent enzyme system concerned in the release of iron from transferrin.

Platelet–Leukocyte Interaction: Selective Binding of Thrombin-Stimulated Platelets to Human Monocytes, Polymorphonuclear Leukocytes, and Related Cell Lines

By T.W. Jungi, M.O. Spycher, U.E. Nydegger, and S. Barandun

The association of platelets with leukocytes was investigated, using gel-filtered platelets stimulated with thrombin and then fixed with formaldehyde. Evidence is presented that stimulation of gel-filtered platelets with low concentrations of thrombin (0.01 to 0.1 U/mL) induces the expression of surface determinants interacting strongly with monocytes and polymorphonuclear leukocytes (PMNs) but only weakly with lymphocytes. Both monocyte–platelet binding and PMN–platelet binding occurred at 37 °C and more intensively at 0 °C; it was Ca^{2+}-dependent and was unaffected by the addition of sodium azide. The binding also occurred with the monocytoid cell lines HL 60 and U 937 in exponential growth and was much less two days after induction of terminal differentiation by phorbol myristate acetate (PMA). No other tested cell lines (B cells, T cells, and myeloid cells) bound thrombin-stimulated platelets. Monocyte-derived macrophages kept in culture for one week also exhibited reduced binding of thrombin-stimulated platelets. IgG and fibronectin could be ruled out as ligands that mediate binding.

© 1986 by Grune & Stratton, Inc.

THE INTERACTION of platelets with leukocytes is poorly characterized. During isolation of mononuclear cells, platelets associate with leukocytes, particularly monocytes, but the potential physiological significance of this interaction has not been elucidated. Although earlier investigations pointed to an enhancing effect of platelets in adherence of monocytes to plastic surfaces, the requirements of this interaction were not studied in detail.[1] More recently, association of platelets with lymphocytes and monocytes hampered investigations of the surface properties[2-4] and metabolic activity[5] of these cells, and recommendations were made for obtaining platelet-free lymphocyte[2] or monocyte[3,5] preparations In addition, an increased association of platelets with monocytes and polymorphonuclear leukocytes (PMNs) (so-called satellitism) has been observed clinically, particularly in disorders of an autoimmune nature[6-8] The association of platelets with leukocytes may be complex, and various different ligands may exist, some of which are involved in a certain stage of platelet stimulation or activation only and which selectively interact with a defined leukocyte population, subpopulation, or cells of a restricted differentiation stage. In the present study, new insights are provided by study of the interaction of resting and thrombin-stimulated platelets, which are then formaldehyde-fixed, with purified lymphocyte and phagocyte populations and human cell lines. During thrombin stimulation in the presence or absence of divalent cations, platelets acquire surface properties suited for binding in a Ca^{2+}-dependent manner to monocytes and PMNs, and to established human cell lines related to both of these. Evidence against an involvement of fibronectin and immunoglobulin G (IgG) as ligands mediating the binding will be presented.

MATERIALS AND METHODS

Preparation of platelets Citrated individual blood donations collected by our blood bank were used. Buffy coats were obtained within 20 hours after collection by centrifugation at 1,200 g for five minutes at 4 °C. Three parts of buffy coats were syphoned into one part of citrate buffer (102 mmol/L of NaCl, 3 mmol/L of KCl, 30 mmol/L of Na-citrate, 4.8 mmol/L of glucose, pH 6.5) and centrifuged at room temperature for four minutes at 800 g. Platelet-rich supernatants were incubated for 30 minutes at 37 °C, pH 6.5, and gel-filtered at 37 °C on a Sepharose 2B column previously equilibrated with MES-buffer (10 mmol/L of 2-[N-Morpholino]ethanesulfonic acid [MES], 3 mmol/L of KCl, 4 8 mmol/L of glucose, 130 mmol/L of NaCl, and 2 mg/mL bovine serum albumin (BSA), pH 6.5) Gel-filtered platelets were counted on a TOA platelet counter (TOA Medical Electronics Co, Ltd, Japan) and adjusted to 2 5 × 10^9 platelets per milliliter.

For activation of platelets with bovine thrombin (61 NIH-U/mg, Hoffmann La Roche, Basel, Switzerland), the pH of platelets was adjusted to 7.4 One part of platelets was then incubated with four parts of modified Tyrode's buffer (MTB; Tyrode's buffer containing 2 mmol/L of $MgCl_2$, and 2 mg/mL BSA but no $CaCl_2$) (pH 7.4) and one part of thrombin in 0.15 mol/L of NaCl for 30 minutes at 37 °C without stirring. The incubation mixture was then added at room temperature to 18 parts of 1.3% formaldehyde in MTB, pH 6.5, without BSA, and chilled for one hour at 4 °C Fixed platelets were washed twice with MTB, pH 6 5, without BSA and finally resuspended in MTB, pH 7.4, of a concentration of 1.1 × 10^9/mL. They were stored in the presence of 0 05% Na-azide for up to two days Prolonged storage reduced the capacity of thrombin-stimulated platelets to associate with monocytes.

Preparation of monocytes. The pellets of the same buffy coats serving for platelet preparation (see above) were the starting material for preparation of monocytes. They were washed twice with citrate buffer and centrifuged at low speed (ten minutes, 200 g) to remove most of the platelets. The pellets were then resuspended in washing solution [phosphate-buffered saline (PBS) containing 13 mmol/L of EDTA, 0.1% wt/vol sodium azide, 1% wt/vol modified gelatin (Physiogel, SRK)] and subjected to centrifugation on Ficoll-Hypaque for isolation of mononuclear cells[9] These were chilled to 4 °C and washed two more times in the cold for thorough removal of platelets. Mononuclear cells (up to 50 × 10^6) were layered on top of discontinuous density gradients of Percoll with densities ranging from 1.066 to 1.060. After centrifugation (600 g for 30 minutes at 4 °C), the cell bands of a density of <1 060 and <1.062 were harvested, pooled, and subjected to further washing at

4 °C. The final monocyte fraction consisted of 65% to 90% monocytes, as defined by staining for nonspecific esterase[10] and Turk solution; the remainder were lymphocytes. The cells were resuspended in RPMI 1640 buffered with HEPES (pH 7.2) and containing 0 5% wt/vol of BSA (RHA) Monocytes were used either in the platelet–leukocyte interaction test or in rosette formation and phagocytosis tests, which are described elsewhere [11,12] In the latter, sheep erythrocytes opsonized with IgG or treated with gelatin and fibronectin were used as targets

Isolation of PMN PMNs were obtained by collecting the top layer of the PMN-erythrocyte pellet of Ficoll-Hypaque tubes used for monocyte isolation. The layer was washed, and erythrocytes were lysed with ammonium chloride (0.83% wt/vol for 15 minutes at 37 °C). After two more washes, the PMNs were resuspended in RHA and used in the platelet interaction test; they were 98% pure, and >95% cells excluded Trypan blue.

Culture of mononuclear phagocytes Mononuclear cells were isolated from buffy coats as described, except that sterile conditions were used and washing solution was replaced by PBS containing 0.3 mmol/L of EDTA.[13] The cells were resuspended in HEPES-buffered RPMI 1640 containing 2% vt/vol pooled heat-inactivated (30 minutes at 56 °C) human group AB serum and placed in 75-cm^2 culture flasks (Falcon, Oxnard, Calif). After one hour of incubation, nonadherent cells were removed by washing with RPMI 1640, and adherent cells (≈80% to 95% monocytes) were cultured exactly as described.[14] Following an overnight culture with RPMI 1640 containing 15% heat-inactivated group AB serum, the cells were dislodged from the flask and put in bags made of teflon foil (type 100 A; Angst & Pfister, Zurich, Switzerland). The sealed bags were kept at 37 °C in an atmosphere of 5% CO_2 for one week, by which time monocytes had matured to macrophages

Culture of established cell lines. Established human cell lines of the collection of the Institute for Clinical and Experimental Cancer Research, Berne, Switzerland, were used. These included T cell lines MOLT 4 and Jurkat, B cell lines Raji and Namalva, myeloid line K562, and myelomonocytoid lines U 937 and HL 60. They were cultured in RPMI 1640 supplemented with HEPES (10 mmol/L), glutamine (2 mmol/L), penicillin (100 IU/mL), streptomycin (100 μg/mL), sodium pyruvate (1 mmol/L), and 20% fetal calf serum (FCS) for obtaining rapid growth and 10% FCS for maintenance and slow proliferation, respectively.

For induction of terminal differentiation of U 937 and HL 60 cells, 4β-phorbol 12-myristate 13-acetate (PMA) was used.[15,16] Two and a half million cells in 25-cm^2 area flasks (in 10 mL) were treated with PMA (16 mmol/L), 20 to 44 hours later, cells were harvested for use in the platelet interaction test.

Platelet–leukocyte interaction test. Fifty microliters of the platelet suspension were admixed to 50 μl of RHA and 100 μl of cell suspension adjusted to 3 to 5 × 10^6 cells/mL in 12 × 75 mm Minisorp tubes (Nunc, Roskilde, Denmark). These were incubated for 30 minutes (unless otherwise indicated) at 37 °C or 0 °C under rocking conditions Aliquots were then placed in a Neubauer chamber and immediately scored for the association of more than two platelets per cell. Another aliquot was mixed with Turk's solution and then evaluated for the platelet–cell association. In each case, 200 to 400 viable single cells were scored. In some experiments, ^{51}Cr-labeled platelets were allowed to interact with monocytes, and the incubate was separated into free platelets and leukocytes carrying bound platelets, using zonal rate centrifugation over sucrose [17] The procedure allowed determination of the mean number of platelets associating with leukocytes.

Assessment of binding of fibronectin (Fn) to gel-filtered platelets. Fn was purified by affinity chromatography on modified gelatin coupled to sepharose 4B,[18] lyophilized, and stored at 4 °C. It was pure, as determined by gel electrophoresis under reducing conditions Only one band, representing a molecular weight of 220,000, was observed Fn was labeled with ^{3}H by reductive methylation[19] and stored at −70 °C in aliquots. Specific activity was 50,000 to 70,000 cpm/μg, ^{3}H-Fn was always centrifuged for five minutes at 11,000 g and at room temperature before use.

To 50 μL of gel-filtered platelets (2.5 × 10^9/mL), 150 μL of MTB pH 7.4, 50 μL of ^{3}H-Fn in MTB, and 50 μL of thrombin in 0.15 mol/L of NaCl were added, and the tubes were incubated at 37 °C for 30 minutes without stirring. Then, 150 μL of a mixture of dinonylphthalate/dibutylphthalate (1·2 56) was underlayered, and the tubes were centrifuged at 11,000 g for 30 seconds, separating the platelets from the water phase through the phthalate mixture. Aliquots of the supernatants were counted, and the tubes were inverted. After removing traces of supernatant using absorbent paper, 150 μL of 0 5% Triton X-100 and two drops of xylol were added to the sediments prior to solubilization with a sonifier (Branson Sonic Co, Danbury, Conn). Solubilized platelets were transferred to a counting vial, and radioactivity was measured in a Packard TriCarb 2450 Liquid Scintillation Spectrometer (Downers Grove, Ill)

Interaction of Fn with gelatinized erythrocytes Erythrocytes, which were tanned and gelatinized essentially as described,[20] (E^s-T-G), were incubated with graded amounts of Fn Under the conditions used, 6% of the added Fn became bound to E^s-T-G as assessed radiometrically. E^s-T-G charged with subagglutinating Fn doses (≤10 μg/mL) were used in rosette formation assays. Agglutinating doses were used in hemagglutination inhibition tests to determine the active titer of goat anti-human Fn antibodies (purchased from Calbiochem, Behring Diagnostics, La Jolla, Calif).

RESULTS

Interaction of thrombin-stimulated, fixed platelets with monocytes. Human platelets stimulated with thrombin and then fixed with formaldehyde were assessed for their capacity to adhere to purified, platelet-poor, autologous monocytes. Although unstimulated platelets had little tendency to associate with monocytes, the platelets acquired the capacity to adhere to monocytes upon stimulation with increasing amounts of thrombin (Fig 1). This adherence was observed microscopically whether the platelet–monocyte mixtures were evaluated unstained immediately after incubation (30 minutes at 37 °C), stained with Turk's solution, or chilled and then stained. At 0.02 U/mL of thrombin, the maximal proportion of platelet-bearing monocytes was reached, but additional numbers of platelets were observed per responsive monocyte when the thrombin concentration was further increased.

The time course of the platelet–monocyte interaction at 0 °C and at 37 °C, using formaldehyde-fixed platelets previously stimulated with 0.02 U/mL of thrombin, is shown in Fig 2; a maximal proportion of platelet-bearing monocytes was observed after 10 to 15 minutes. The proportion of platelet-bearing monocytes was reproducibly higher when the interaction occurred in the cold (0 °C). Sodium azide (20 mmol/L) added to the monocyte–platelet mixtures did not influence monocyte–platelet association.

Role of plasma fibronectin (Fn) in platelet-monocyte interaction. In view of previous findings that Fn binds to stimulated platelets[21,22] and that monocytes express cell surface receptors for this protein,[20,23] a role of plasma Fn in the platelet–monocyte interaction was sought.

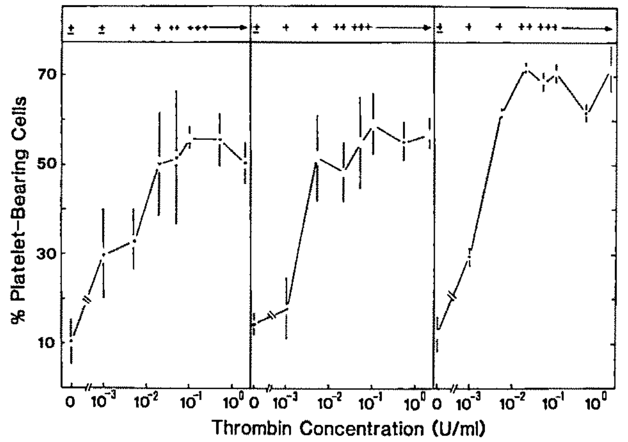

Fig 1. Thrombin-stimulated platelets, then formaldehyde-fixed, bind to monocytes. The percentage of cells bearing more than two platelets (means ± 1 SD), as assessed microscopically, after 60-minute incubation in medium RHA, is plotted as a function of the thrombin concentration used for platelet stimulation. In addition, the degree of platelet association per single monocyte was scored arbitrarily from − to + + + and is indicated in the top row panel. Left panel, unstained preparations; middle panel, cells stained with Turk's solution; right panel, tubes chilled in ice before microscopic examination.

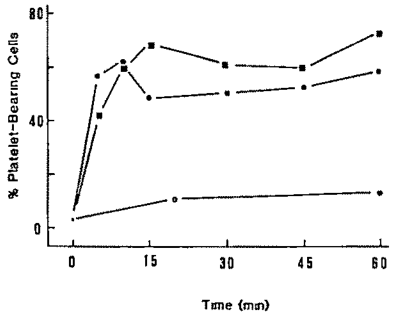

Fig 2. Kinetics of the binding of thrombin-stimulated and control platelets to monocytes in suspension. Incubation of monocytes and stimulated platelets was performed at 37 °C (●) and 0 °C (■); incubation of monocytes and control platelets was performed at 37 °C (○).

First, the amount of exogenous Fn bound to platelets stimulated by various amounts of thrombin was estimated. In agreement with previous work,[21] Fn binding reached a maximum when 0 2 U/mL thrombin was used in the presence of 2 mmol/L $MgCl_2$ while 15 mg/mL of Fn was allowed to react with 2.5 × 10^9 platelets per milliliter. Under conditions of maximal platelet–monocyte association (0.02 U/mL of thrombin), only 55 fg Fn bound per platelet. In the presence of 5 mmol/L of EDTA, binding was reduced by >90%. Using thrombin-stimulated platelets and then formaldehyde-fixed platelets rather than native platelets, saturation of ^{3}H-Fn binding was reached at the same thrombin concentration, but binding was diminished by 40% to 60%.

Second, the effect of Fn added either during thrombin stimulation of the platelets or during the interaction phase between platelets and monocytes was assessed. In both cases, exogenous Fn did not increase the proportion of platelet-bearing monocytes (Table 1, experiment 1). On the contrary, when platelet–monocyte mixtures were subjected to zonal rate centrifugation on sucrose, ^{51}Cr-labeled platelets stimulated with high thrombin concentrations in the presence of excess Fn were associated in lower numbers with monocytes than were their counterparts prepared in the absence of exogenous Fn (data not shown).

Third, goat anti-Fn antibodies were co-incubated with thrombin-stimulated platelets and monocytes. The antibodies were nonreactive with monocyte Fc receptors, as we have verified in Fc receptor-mediated phagocytosis inhibition experiments. Antibodies were shown to block the agglutination of E*-T-G mediated by Fn, yet they failed to inhibit

the association of stimulated platelets with monocytes (Table 1, experiment 2).

Role of IgG in the platelet–monocyte interaction. The possibility that IgG associating with platelets[24] interacts with monocyte Fc receptors was tested by co-incubating thrombin-stimulated platelets and monocytes with IgG at concentrations blocking Fc-receptor-mediated rosette formation and erythrophagocytosis completely. In the presence of 8 mg/mL IgG, 54% ± 7% mononuclear cells bound platelets, as compared to 43% ± 14% in the absence of IgG. Likewise, platelet–monocyte association occurred in the presence of 25% heat-inactivated serum as well (not shown).

Divalent cation requirements for platelet–monocyte association. The role of divalent cations was tested by including cation-chelating agents either during thrombin stimulation or during the platelet–monocyte interaction phase. Simultaneous exposure of platelets to EDTA and thrombin for 30 minutes prior to fixation yielded no significant reduction in monocyte adhesiveness as compared with platelets stimulated in the absence of EDTA (Table 2, experiment 1). Platelets preincubated for 30 minutes in 5 mmol/L of EDTA, then stimulated with thrombin, behaved in the same manner as did stimulated platelets not exposed to EDTA. In contrast, if either EDTA or EGTA were included during the interaction of stimulated platelets with monocytes, even fewer monocytes bound such platelets than occurred if monocytes were allowed to interact with unstimulated platelets in Ca^{2+}-sufficient and Mg^{2+}-sufficient medium (Table 2, experiment 2), suggesting that the interaction of stimulated platelets with monocytes is strictly Ca^{2+} dependent.

Binding of thrombin-stimulated platelets to various cell types derived from human blood Even if platelets had little tendency to bind to lymphocytes contaminating the monocyte preparation, it was possible that certain lymphocyte subpopulations absent from the tested density fractions also had the capacity to bind stimulated platelets. Therefore, lymphocyte-enriched cell fractions were also washed and tested for their capacity to bind stimulated platelets. Although in all fractions (except Percoll density-gradient fraction II), most monocytes bound stimulated platelets, only a small subpopulation of lymphocytes (5% to 10%) did so (Fig 3). Such lymphocyte–platelet interaction, however, was largely resistant to a subsequent treatment with EDTA.

In another set of experiments, the capacity of purified PMNs to bind stimulated platelets was tested. PMNs appeared to be capable of binding stimulated platelets, but higher thrombin concentrations (0.1 U/mL) were required for rendering platelets optimally adhesive to PMNs (Fig 4). In addition, the number of platelets per PMN was consistently smaller than the number binding to monocytes. The platelet–PMN association was also observed at 0 °C, but not in the presence of EDTA (Table 3).

Binding of thrombin-stimulated platelets to cultured cells. Freshly isolated monocytes were further matured to macrophages by means of teflon bag cultures.[14] Mature macrophages had little tendency to bind stimulated platelets, despite their increased surface area (Table 4). The same macrophages eagerly ingested erythrocytes sensitized with IgG or with IgM and complement (not shown). Established cell lines of various origin were also tested for their capacity to bind thrombin-stimulated platelets. Table 4 shows that the monocyte-like cell lines (U 937 and HL 60) bound thrombin-stimulated platelets. The tendency to bind platelets was also Ca^{2+} dependent and restricted to thrombin-stimulated platelets. Preferential binding was observed with cells in exponential growth; when terminal differentiation of U 937 and HL

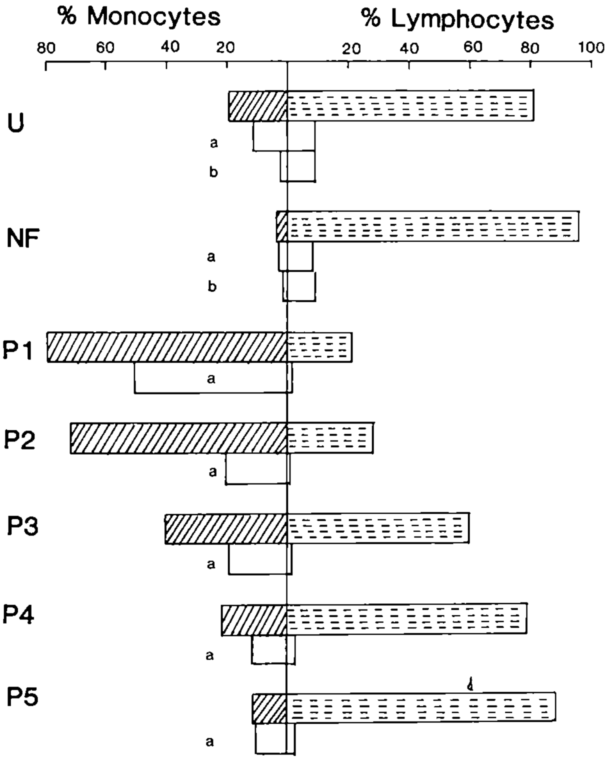

Fig 3. Binding of stimulated platelets by monocytes and lymphocytes in unseparated mononuclear cells (U), in nonadherent mononuclear cells (NF), and in different density fractions recovered from a discontinuous Percoll gradient The hatched and stippled bars show the proportion of monocytes and lymphocytes, respectively, in each fraction; the open bars show the proportion of monocytes and lymphocytes, respectively, within the whole fraction binding more than two platelets in the absence (a) or presence (b) of 5 mmol/L of EDTA.

60 was induced by PMA, the capacity of these cells to bind stimulated platelets gradually waned. No other nonmonocytoid cell line was capable of binding thrombin-stimulated platelets. Thus, the interaction of stimulated platelets with cellular surfaces is restricted to surfaces of professional phagocytes in certain defined stages of differentiation and to that of established cell lines closely related to phagocytes.

DISCUSSION

The interactions between platelets and phagocytes are ill-defined. Although platelets are the first cellular elements to get involved in areas in which vascular basement membrane has been exposed, phagocytes soon follow.[1] Phagocytes essentially determine the cellular and molecular composition of inflamed tissue, and platelets too are found in areas of inflammation such as the synovial tissue of rheumatoid arthritis patients.[25] Phagocytes generate mediators affecting platelets,[26] and both phagocytes and platelets are capable of producing and responding to a variety of substances of the arachidonic acid metabolism.[5,27,28] Furthermore, the surface receptor spectra of phagocytes and platelets have much in common with each other.[20-24,29,30] In the laboratory, platelets often contaminate preparations of phagocytes, particularly monocytes, and special procedures are necessary to prevent association of platelets with monocytes.[3,5,31]

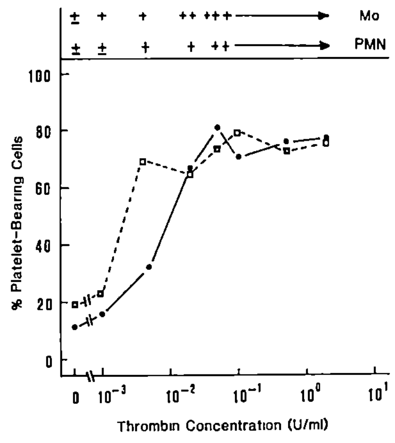

Fig 4. Binding of stimulated platelets, then formaldehyde-fixed, to PMNs as a function of the thrombin concentration used for stimulation. Purified PMN were incubated for 30 minutes at 37 °C and then assessed after being stained with Turk's solution (●). For comparison, the proportion of platelet-bearing monocytes in a parallel experiment with the same platelets is shown (□). The degree of platelet-association per single PMN or monocyte, respectively, is expressed in arbitrary scores from — to + + + and is indicated in the top panel.

In view of these considerations, it was not unexpected when we found that, in vitro, platelets associated with monocytes and PMNs in a specific and reproducible fashion. The finding is based on studies with gel-filtered platelets that were stimulated with thrombin under conditions that did not lead to aggregation and that were then fixed with formaldehyde. This fixative agent, which cross-links certain surface determinants, leaves various platelet properties unaffected, including antigenic properties,[32] the capacity to bind myxoviruses,[33] reactivity in lectin-induced aggregation tests,[34] and involvement in aggregation when precoated with fibrinogen and co-incubated with native platelets and thrombin.[35] Yet formaldehyde-fixed platelets fail to aggregate upon stimulation with thrombin[34] and thus are suitable for studying their interaction as single particles with leukocytes.

Platelets acquired adhesiveness to monocytes when stimu-

lated with thrombin in a dose-dependent manner. The lowest dose of thrombin which induced a significant adhesiveness to monocytes was 0.001 U/mL; <0.02 U/mL yielded an optimal response. For adherence to neutrophils, thrombin concentrations ten times higher were required to achieve the same binding properties. Thrombin-stimulated platelets directly bound to phagocytes rather than to contaminating native platelets; the latter had been thoroughly removed during phagocyte purification. Unstimulated, fixed platelets had little tendency to associate with phagocytes; it is our assumption that the few platelets in an unstimulated population which nevertheless adhered represented a subpopulation that had undergone spontaneous stimulation, most probably during centrifugation. This assumption is supported by the finding of Perussia et al[3] that the association of monocytes with platelets in Ficoll-Hypaque–purified mononuclear cell preparations can be prevented by pretreating the blood with aspirin and EDTA, thus limiting spontaneous platelet stimulation.

Which are the surface determinants on stimulated platelets that mediate the observed binding? Although further studies must solve this question, we can at least rule out some of the possibilities. For example, fibronectin does not appear to be involved, although Fn is released during thrombin stimulation and is bound by the platelet surface[21,22,36] and although phagocytes do have receptors for Fn.[20,23] The arguments against Fn involvement in our model are several-fold. Because platelet–monocyte association occurs without the addition of Fn, Fn would have to be surface-bound either on platelets or on monocytes. That it would be bound to monocytes is highly improbable since our conditions of monocyte washing (in the presence of EDTA) would appear to prevent this, and the time interval in the interaction test would be too short to allow Fn synthesis by monocytes. Moreover, gelatinized erythrocytes were not rosetted by monocytes (data not shown), although Fn may serve as a bridging molecule between gelatin and monocytes (ref. 20 and this study), and although the same erythrocytes avidly bound radiolabeled Fn. Thus, Fn would have to be surface-exposed by platelets during thrombin stimulation. However, little Fn binding and insignificant serotonin release were observed when platelets were stimulated with 0.02 U/mL of thrombin although these platelets were optimally adhesive to monocytes. Moreover, the addition of free Fn to platelet–monocyte mixtures did not inhibit the binding as would be expected if free ligand were to compete with surface-bound Fn. Regardless whether a putative Fn ligand were of platelet or monocyte origin, its ligand role would be affected by co-incubation with anti-Fn antibodies but not with the selective Ca^{2+} chelator EGTA.[20] However, platelet–monocyte interaction was blocked completely by 5 mmol/L of EGTA (Table 2), proving its strict Ca^{2+} dependency during the platelet–monocyte interaction phase; in contrast, it was unaffected by the addition of Fn-antibodies at concentrations effectively blocking the agglutination of gelatinized erythrocytes in the presence of Fn. Our findings do not rule out the possibility that Fn may participate in the platelet–monocyte interaction under other experimental conditions.

Another adhesive protein involved in platelet function is fibrinogen (Fg).[37] Formaldehyde-fixed platelets were shown to interact with fresh, stimulated platelets by virtue of their Fg receptor, recognizing Fg on their native counterparts.[37] Moreover, mononuclear phagocytes were reported to bind fibrin and/or fibrinogen specifically,[38-40] and it was suggested recently that human monocytes express the GP IIb/IIIa complex, the platelet Fg receptor.[41,42] However, this hypothesis is still controversial,[4] and our preliminary results did not favor an involvement of Fg in platelet–monocyte interaction. In these experiments, ADP-stimulated, fixed platelets that are known to express Fg receptors[37] failed to adhere to monocytes regardless of the amount of exogenous Fg added during stimulation (data not shown).

A further potential mediator for platelet–monocyte interaction is IgG, since monocytes bear IgG-Fc receptors and platelets have been reported to carry significant amounts of platelet-associated IgG. In particular, a cohort of aged platelets is said to carry increased amounts of IgG, probably natural antibodies against structures exposed on old platelets.[43] However, several lines of evidence militate against an involvement of IgG in the platelet–monocyte interaction: First, EDTA abolishes the adherence of platelets to monocytes (Table 2) and PMNs (Table 3) but not the binding of IgG coated targets, including platelets[17] to monocytes. Second, the described adherence phenomenon also occurs in the presence of 25% normogammaglobulinemic heat-inactivated human serum or 8 mg/mL IgG. However, both completely block the monocyte rosette formation with IgG-coated erythrocytes (T.W. Jungi, unpublished observations, 1983). Third, the binding of IgG-coated particles provides an obligatory signal for internalization of the bound particle, but neither we nor others[5] observed internalization of monocyte-bound platelets. Finally, it is difficult to comprehend how thrombin stimulation would alter the reactivity of platelets in such a dramatic way if IgG were the ligand mediating the binding. This evidence against involvement of IgG in the described platelet–monocyte interaction does not exclude the possibility that certain forms of platelet satellitism observed clinically are caused by platelet-specific antibodies or platelet-associated immune complexes.[44]

Thrombin-stimulated platelets seem to adhere to monocytes and PMNs without engaging their metabolism, because the adherence reaction occurs rapidly regardless of the temperature or of the presence of sodium azide. However, it is selective, insofar as it was seen with monocytes and PMN exclusively. Only a small lymphocyte subpopulation (which was not further characterized) bound stimulated thrombocytes; this binding was not Ca^{2+} dependent. Monocytes that had matured to macrophages in vitro exhibited a diminished capacity to bind stimulated platelets despite an increased activity in ingesting IgG-sensitized target cells. On the other hand, cell lines representing undifferentiated precursors of monocytes and/or neutrophils avidly bound stimulated platelets; this binding was also Ca^{2+} dependent and occurred at 0 °C as well as at 37 °C. Because cultured macrophages are highly adherent but the above cell lines are not, the capacity to bind stimulated platelets is not an expression of the adherence properties of phagocytes. Because all other cell lines tested, representing precursors of the T cell, B cell, and erythrocyte lineage, were incapable of binding stimulated gel-filtered platelets, it appears that the capability of binding thrombin-stimulated platelets is a property unique to monocytes, PMNs, and cell lines related to them. The presence of a monocyte subpopulation failing to bind platelets (Figs 1 and 3) and the reduced efficiency of cultured macrophages and PMA-treated myelomonocytoid cell lines in the platelet-binding test suggest that the capacity of phagocytes to interact with thrombin-stimulated platelets is further restricted to certain stages of differentiation.

Amplification of Genes Encoding Human Myeloid Membrane Antigens After DNA-Mediated Gene Transfer

By A. Thomas Look, Stephen C. Peiper, Edwin C. Douglass, Jeffrey M. Trent, and Charles J. Sherr

Spontaneous amplification of genes encoding two different human myeloid surface antigens was observed after DNA-mediated gene transfer of cellular DNA from the human myeloid cell line HL-60 into NIH-3T3 mouse fibroblasts. Transformed recipient cells with highly amplified expression of either of two donor membrane polypeptides, gp150 or p67, were isolated with a fluorescence-activated cell sorter (FACS), using monoclonal antibodies specific for human myeloid cells. Immunoprecipitation of enzymatically radioiodinated polypeptides from the surface of transformed NIH-3T3 cells confirmed that expression of these proteins was amplified tenfold to 20-fold in comparison to their expression on human myeloid cell lines. The cellular DNA of cloned secondary and tertiary transformants expressing high levels of gp150 and p67 contained amplified sets of DNA restriction fragments that hybridized with human repetitive DNA sequences. Cytogenetic analysis of subclones overexpressing gp150 revealed extrachromosomal double minutes (DMs), whose presence correlated with the unstable expression of the membrane polypeptide. Human sequences in gp150-positive clones did not localize to chromosomes, consistent with their association with extrachromosomal DMs. By contrast, p67-positive subclones stably expressed the antigen, and in situ hybridization to metaphase spreads demonstrated that amplified human DNA sequences were integrated into a specific marker chromosome. Cytogenetic analysis of the parental NIH-3T3 subclone used in these studies disclosed DMs in a low percentage of metaphases, suggesting that the recipient cells have a propensity for amplifying donor DNA.

GENE amplification is an important mechanism for the development of drug resistance in cultured cells exposed to antimetabolites.[1-4] In addition, certain tumor cell lines have been found to contain amplified cellular oncogenes, including N-*myc*,[5-7] c-*myc*,[8,9] and c-*abl*,[10] which presumably confer a proliferative advantage to cells both in vitro and in vivo. When gene amplification is manifested by aberrant banding regions (ABRs), expression of the amplified DNA sequences tends to be stable.[11] If double minute chromatin bodies (DMs) are involved, there is unequal segregation of the amplified genes under nonselective conditions, resulting in an unstable phenotype.[4,12]

Amplification of genes can also occur spontaneously. For example, methotrexate-resistant cells with a 50-fold increase in copies of the dihydrofolate reductase gene were isolated with a fluorescence-activated cell sorter (FACS) after staining with a fluoresceinated conjugate of methotrexate.[13] Similarly, spontaneous amplification of the gene encoding the human T cell membrane antigen Leu-2 (or T8) was observed after DNA-mediated gene transfer of human DNA sequences into mouse cells followed by flow cytometric selection of Leu-2-positive recipients with a fluorescein-conjugated antibody.[14,15] In the latter case, high but unstable levels of expression of the Leu-2 antigen in recipient cells were associated with the presence of DMs, implying that the transferred gene was amplified extrachromosomally

We recently used DNA-mediated gene transfer and cell-sorting procedures to isolate mouse cell clones that had acquired human DNA sequences coding for a myeloid differentiation antigen, gp150.[16] Mouse NIH-3T3 cells were co-transfected with high-mol-wt DNA from the human HL-60 promyelocytic cell line together with a molecularly cloned feline sarcoma virus (FeSV) containing the v-*fms* oncogene. The v-*fms* transforming gene, which served as the dominant selectable marker, permitted cells that had acquired exogenous DNA to overgrow nontransformed fibroblasts. Because most transformed cells incorporated ~1,500 kilobases (kb) of human DNA, or ~0.1% of the human genome,[17] we were able to select antigen-positive recipient cells by automated cell-sorting procedures performed with four monoclonal antibodies directed to different gp150 epitopes. Sequential rounds of DNA-mediated gene transfer and cell sorting were used to isolate a family of secondary and tertiary mouse cell transformants, each of which contained a limited but characteristic set of human DNA restriction fragments presumed to represent the gene coding for gp150.

In the course of these experiments, we identified recipient mouse cell clones that expressed significantly higher levels of gp150 than did the human HL-60 donor cells. Experiments performed with another myeloid antigen, p67, yielded similar results. We now show that the relative overexpression of both gp150 and p67 in recipient mouse cells is associated with specifically amplified human gene sequences The amplified sequences appeared to be associated with DMs in recipient cells that unstably overexpressed gp150 and were integrated at a specific chromosomal locus in cells demonstrating stable amplification of p67.

MATERIALS AND METHODS

Cell lines. NIH-3T3[18] [subclone 7 derived by Dr Douglas Lowy[19]] and L (*tk*−) cells[20] were grown as monolayer cultures in Dulbecco's modified Eagle's medium (DMEM) containing 10%

fetal calf serum (FCS), penicillin (100 μg/mL), and streptomycin (100 μg/mL). The human myeloid cell lines HL-60[21] and KG-1a[22] were maintained in RPMI 1640 medium containing 15% FCS and antibiotics. Transformed L cells were grown in selective media containing hypoxanthine (100 μmol/L), aminopterin (0.4 μmol/L), and thymidine (16 μmol/L) (HAT). Transformed NIH-3T3 cells were cultured in medium containing 5% FCS

Transfection of high-mol-wt DNA. DNA from the cloned McDonough strain of FeSV containing the v-*fms* oncogene[23] was co-transfected with 5 μg of sheared cellular DNA into NIH-3T3 cells, using the calcium phosphate technique.[19,24] After 18 hours of incubation with DNA precipitates, the cells were trypsinized and plated into 75-cm^2 T-flasks with medium containing 5% FCS. Foci of transformed cells were enumerated 12 days later and were then allowed to overgrow the monolayer of untransformed NIH-3T3 recipients. The efficiency of transformation in this system is ~2,000 foci per microgram of FeSV DNA[23,25] L (*tk*−) cells were co-transfected with the herpes simplex *tk* gene and 5 μg of sheared cellular DNA. After 18 hours of incubation, the cells were trypsinized and seeded into 75-cm^2 T-flasks. HAT medium was added 24 hours later and was changed every three or four days. Transfected NIH-3T3 or L cells from 7 to 20 confluent flasks were trypsinized and pooled for selection by FACS.

Monoclonal antibodies and flow cytometry. Transformants were sorted by flow cytometry after staining with either of two monoclonal antibodies (MY7 or MY9; Coulter Immunology, Hialeah, Fla) that react with epitopes of surface molecules expressed by human myeloid cells.[26-28] Transformants isolated with the two antibodies were tested by flow cytometry for binding of the monoclonal antibodies DU-HL60-4,[29] obtained from Dr Richard S Metzgar of Duke University (Durham, NC); MCS.2[30] obtained from Dr Jun Minowada of Loyola University (Chicago, Ill), SJ-D1,[31] obtained from Dr Joseph Mirro of St Jude Children's Research Hospital (Memphis, Tenn); and L4F3 and L1B2[32] obtained from Dr Irwin D Bernstein of the Fred Hutchinson Cancer Research Center (Seattle, Wash) NIH-3T3 transformants were also tested for binding of the monoclonal antibody SM2.6.3, which recognizes an epitope of the cell surface glycoprotein encoded by the v-*fms* oncogene.[25,33] Indirect immunofluorescence labeling, flow cytometric analysis, and cell sorting were performed as previously described.[25]

Detection of human repetitive sequences in transfected mouse cell DNA. Cellular DNAs were digested with various restriction endonucleases (Bethesda Research Laboratories, Gaithersburg, Md), separated by electrophoresis in 0.8% agarose gels, and transferred to nitrocellulose [34] Human DNA containing highly repetitive sequences was prepared, labeled to a specific activity of 1×10^8 dpm/μg by nick translation, and used in blot hybridization under stringent annealing conditions.[16]

Radioiodination of cell surface proteins. Live HL-60, KG-1a, or transformed NIH-3T3 cells were iodinated with lactoperoxidase, and detergent lysates were immunoprecipitated and separated by electrophoresis in polyacrylamide gels containing sodium dodecyl sulfate (SDS).[16] The positions of radiolabeled proteins were determined by autoradiography of the dried slab gels by using protein standards of known mol wt.

Cytogenetic analysis and in situ hybridization Chromosomes were harvested from colcemid-treated NIH-3T3 transformants, and air-dried slides were prepared.[35] The autoradiographic images of 50 mitotic cells from the gp150 and p67 positive clones were examined following in situ hybridization with ^{3}H-labeled human repetitive DNA by methods previously described.[36] Prior to in situ hybridization, the cells were stained with quinacrine (Q-banding) and were photographed for positive reference Cells were then hybridized for 16 5 hours at a final DNA concentration of 0 5 μg/ml, followed by exposure for 14 days and subsequent autoradiographic development

RESULTS

Isolation of mouse cell transformants overexpressing human myeloid cell surface antigens. DNA from the human promyelocytic cell line, HL-60, was co-transfected into mouse NIH-3T3 cells with the cloned v-*fms* gene, and recipient cells were isolated by flow cytometry, using monoclonal antibodies to myeloid-specific antigens. Serial rounds of transfection and sorting[16] were used to obtain two classes of tertiary transformants that reacted with the gp150-specific monoclonal antibody, MY7. The two classes of MY7-positive cells included a major population with fluorescence intensity similar to that seen with donor HL-60 cells and a minor population with markedly increased fluorescence. When agar subclones derived from these cell populations were retested for MY7 binding, most showed a homogeneous pattern of MY7 antibody fluorescence, similar to that observed in primary and secondary transformants (results with subclone SJ-150-A in Fig 1, panel A). By contrast, a small proportion of the subclones showed increased MY7 binding with a heterodisperse pattern of fluorescence intensity. The brightest cells from one of these subclones (SJ-150-B) were sorted three more times, and the resulting population was enriched for highly fluorescent cells (Fig 1, panel A). Amplified gp150 expression by subclone SJ-150-B was also observed with three other gp150-specific antibodies, DU-HL60-4, MCS.2, and SJ-D1 (data not shown).

In parallel experiments, we used the monoclonal antibody MY9[28] to test recipient mouse cells for the expression of another myeloid differentiation antigen, a polypeptide of 67 kd that is also expressed on the surface of HL-60 cells. This antigen is provisionally designated "p67" because the nature of its posttranslational modification, if any, is presently unclear. Pooled L cell transformants co-transfected with HL-60 DNA and the cloned herpes simplex thymidine kinase gene were selected in HAT medium, and MY9-positive populations were isolated after cell sorting. DNA from a primary transformant selected for reactivity with MY9 was then co-transfected with the v-*fms* gene into NIH-3T3 cells, and pooled secondary transformants were sorted with the same monoclonal antibody. After five rounds of sorting, the selected cells were uniformly positive for MY9 binding. Retesting of subclones derived from agar colonies demonstrated a threefold increase in fluorescence as compared to the negative autofluorescence profile obtained with the control myeloma protein, as shown for subclone SJ-67-A in Fig 1, panel C.

Although cells with amplified expression of MY9 were not evident in the pooled transformants after five rounds of sorting, the brightest 2% of cells were repeatedly sorted to isolate occasional cells with amplified p67 expression. After six more rounds of sorting, subclones showed uniformly exaggerated levels of MY9 binding and stably expressed high levels of antigen after several months in continuous culture. The fluorescence histogram for one of the latter subclones, SJ-67-B, showed ~40-fold more MY9-specific fluorescence than did control cells stained with myeloma

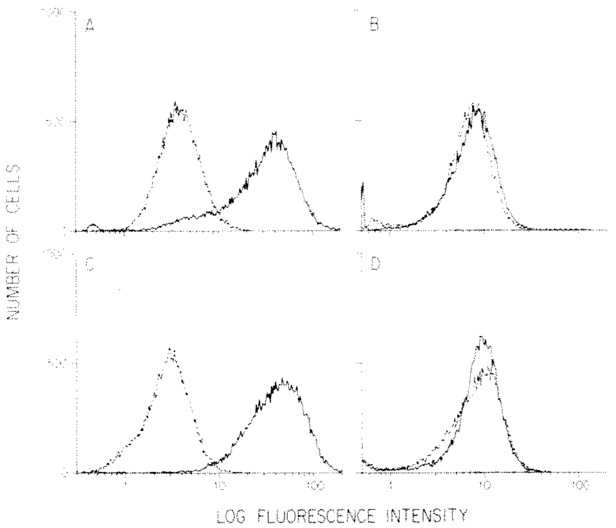

Fig 1. Cell surface expression of human myeloid membrane antigens and the v-*fms*-coded glycoprotein detected by flow cytometry. In each panel, the fluorescence profiles recorded with antibodies specific for epitopes of human myeloid antigens or v-*fms*-coded molecules are compared with the control fluorescence profile obtained with an isotype-matched mouse or rat myeloma protein (..........). Fluorescence profiles obtained with the gp150-specific monoclonal antibody MY7 with transformed NIH-3T3 subclones SJ-150-A (--------) and SJ-150-B (————) are shown in panel A. Analogous results using the p67-specific monoclonal antibody MY9 and subclone SJ-67-A (---------) and SJ-67-B (————) are shown in panel C. Results using monoclonal antibody SM 2.6.3 to a v-*fms*-coded epitope are shown in panels B (SJ-150 clones) and D (SJ-67 clones). Symbols designating the cell lines are the same as those in panels A and C, respectively.

protein (panel C). This subclone also exhibited high levels of binding with the monoclonal antibodies L1B2 and L4F3, whose patterns of reactivity with human myeloid cells are similar to those of MY9. Thus, MY9, L1B2, and L4F3 appear to bind to epitopes encoded by the same human gene.

Because the v-*fms* gene also encodes a transforming glycoprotein that can be detected on the cell surface by flow cytometry,[25,33] we tested each of the four subclones shown in Fig 1 for expression of the v-*fms* gene product. Flow cytometric analysis of surface immunofluorescence using the monoclonal antibody SM2.6.3, specific for a v-*fms*-coded epitope, revealed similar intensities of binding with each of the subclones (panels B and D), in contrast to the marked differences observed for the binding of the antibodies MY7 or MY9. Thus, independently derived subclones exhibited nearly identical levels of the transforming gene product on the cell surface, irrespective of amplified expression of human myeloid antigens.

Although certain NIH-3T3 cell clones showed extremely high levels of binding with monoclonal antibodies MY7 (to gp150) and MY9 (to p67), we were unable to select L cell transformants that "overexpressed" these antigens. After repeated selection of the brightest L cell recipients in multiple rounds of sorting, the fluorescence profiles remained similar to those found with the NIH-3T3 subclones SJ-150-A and SJ-67-A and with donor HL-60 cells. The results obtained with the different recipient cells and dominant selectable markers may reflect a greater propensity of NIH-3T3 cells to overexpress these antigens. From the similar efficiency of transformation by the two different dominant selectable markers,[16] it seems unlikely that these differences arose from screening a greater number of transfection events in the v-*fms*/NIH-3T3 cell system *v* the tk/L cell system.

Immunoprecipitation of the overexpressed surface antigens. Two glycoproteins of 130 kd (gp130) and 150 kd (gp150) can be specifically immunoprecipitated with the antibodies MY7 and DU-HL60-4 from metabolically labeled lysates of both donor HL-60 cells and recipient mouse cell transformants. Kinetic and biochemical analyses established that gp130 is an intracellular precursor that differs in its carbohydrate moiety from gp150, the mature form of the glycoprotein detected on the cell surface.[16] To confirm the flow cytometric evidence for amplified expression of gp150, we radioiodinated live cells with lactoperoxidase and immunoprecipitated detergent lysates with the antibody DU-HL60-4. Figure 2A shows that gp150 molecules were specifically precipitated from plasma membranes of HL-60 cells and from the tertiary transformed NIH-3T3 subclones, SJ-150-A and SJ-150-B. As expected from the flow cytometric results, approximately tenfold more gp150 molecules were precipitated from SJ-150-B cells, as compared with results obtained with an equivalent number of SJ-150-A cells.

The molecular species recognized by the monoclonal antibody MY9 was studied in the human myeloid cell line KG-1a and the MY9-positive secondary transformants SJ-67-A and SJ-67-B. Figure 2B shows that the p67 polypeptide was barely detectable in radioiodinated membranes from either KG-1a cells or SJ-67-A cells. Similar low levels of expression occurred when HL-60 cells were used (data not shown). By contrast, subclone SJ-67-B showing stable amplification of MY9 expression (Fig 1) yielded at least 20-fold more p67 molecules than did equivalent numbers of KG-1a or SJ-67-A cells. In this case, secondary transformants expressing high levels of p67 should prove to be of particular value in the biochemical analysis of the p67 polypeptide.

Amplification of human repetitive DNA sequences. The cellular DNA of secondary mouse cell transformants selected for expression of gp150 possesses a characteristic set of human DNA restriction fragments that are recognized by a probe specific for human repetitive DNA.[16] Because the DNA of independently derived secondary transformants yielded the same human DNA restriction fragments, the human DNA sequences shared by these clones were presumed to encode gp150. To determine if amplified expression of gp150 by tertiary transformants resulted from amplification of the transfected human gene, we performed Southern blot analysis of cellular DNA from subclones SJ-150-A and SJ-150-B (Fig 3). After digestion with the restriction endonuclease *Hind* III, six human DNA restriction fragments were detected in both subclones (lanes 1 and 2). The intensity of hybridization of a human repetitive sequence probe with DNA from subclone SJ-150-B was approximately tenfold greater than that observed with an identical amount of DNA from subclone SJ-150-A, suggesting that

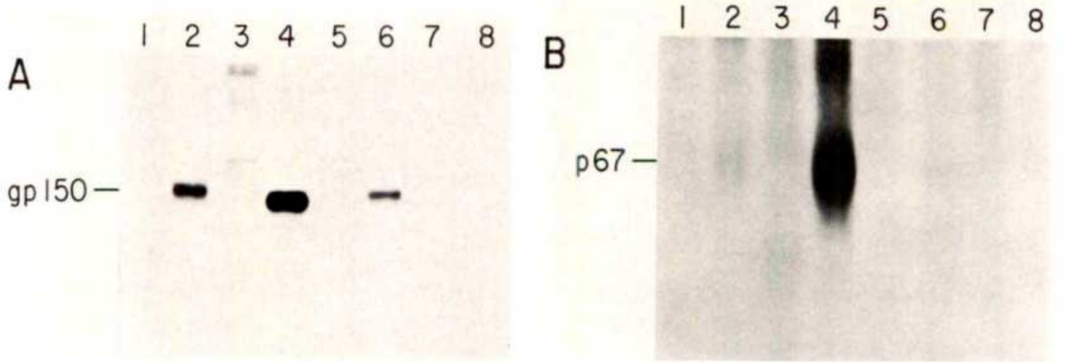

Fig 2. Expression of gp150 and p67 on the plasma membrane of human myeloid cell lines and NIH-3T3 transformants. Viable cells were enzymatically radioiodinated, and detergent lysates were immunoprecipitated. Labeled proteins in immune complexes were denatured and analyzed in polyacrylamide gels containing sodium dodecyl sulfate. Each lane represents immunoprecipitates prepared from 3×10^6 cells. In panel A, lysates of radioiodinated HL-60 cells (lanes 1 and 2), subclone SJ-150-B (lanes 3 and 4), subclone SJ-150-A (lanes 5 and 6), and control v-*fms* transformed NIH-3T3 cells (lanes 7 and 8) were precipitated with control myeloma protein (lanes 1, 3, 5, and 7) or the monoclonal antibody DU-HL60-4 (lanes 2, 4, 6, and 8). In panel B, lysates of radioiodinated KG-1a cells (lanes 1 and 2), subclone SJ-67-B (lanes 3 and 4), subclone SJ-67-A (lanes 5 and 6), and control v-*fms* transformed NIH-3T3 cells (lanes 7 and 8) were precipitated with control myeloma protein (lanes 1, 3, 5, and 7) or the MY9 monoclonal antibody (lanes 2, 4, 6, and 8); mol wts were determined by comparison with stained protein standards run on the same gel.

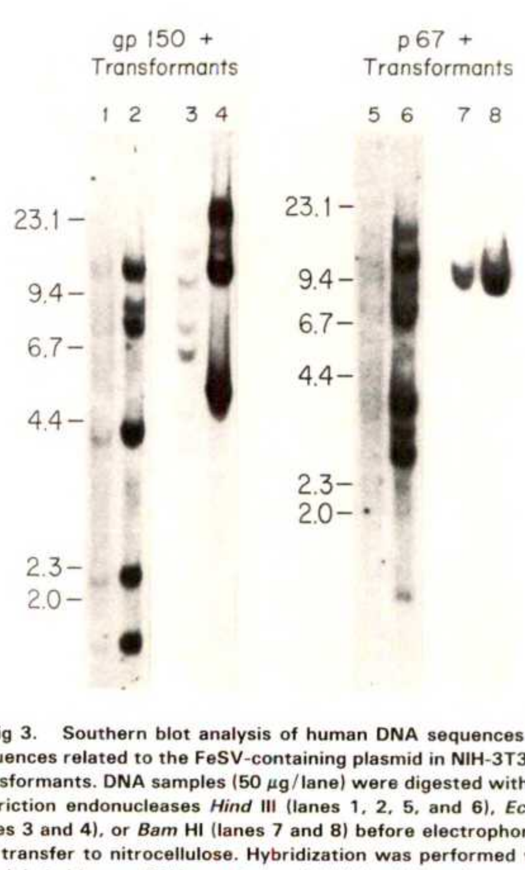

Fig 3. Southern blot analysis of human DNA sequences and sequences related to the FeSV-containing plasmid in NIH-3T3 cell transformants. DNA samples (50 μg/lane) were digested with the restriction endonucleases *Hind* III (lanes 1, 2, 5, and 6), *Eco* RI (lanes 3 and 4), or *Bam* HI (lanes 7 and 8) before electrophoresis and transfer to nitrocellulose. Hybridization was performed with radiolabeled human DNA consisting of highly reiterated sequence families (lanes 1, 2, 5, and 6) or radiolabeled plasmid DNA containing the complete FeSV provirus (lanes 3, 4, 7, and 8). The DNA samples analyzed were from subclones SJ-150-A (lanes 1 and 3), SJ-150-B (lanes 2 and 4), SJ-67-A (lanes 5 and 7), and SJ-67-B (lanes 6 and 8). The positions of bacteriophage λ *Hind* III fragments of known length (noted in kilobase pairs) are indicated to the left of the lanes for each panel.

the sequences encoding gp150 were amplified in SJ-150-B cells. Amplified human DNA restriction fragments were also evident in *Hind* III digests of SJ-67-B DNA, as judged from the intensity of hybridization to similar restriction fragments from SJ-67-A DNA (Fig 3, lanes 5 and 6). As expected, the sizes of the *Hind* III fragments detected with the human repetitive sequence probe differed for transformants selected for expression of gp150 or p67, confirming that these proteins are encoded by different human genes.

DNAs from these subclones were also tested by Southern blotting for amplification of sequences related to the plasmid used as the selectable marker. Nick-translated DNA from a pBR322 vector containing the intact FeSV provirus was hybridized to *Eco* RI digests of DNA from SJ-150-A and SJ-150-B cells (lanes 3 and 4), or to *Bam* HI digests of DNA from SJ-67-A and SJ-67-B cells (lanes 7 and 8). Although each of the subclones expressed similar levels of the v-*fms* gene product on the plasma membrane, amplified sequences related to the FeSV-containing plasmid were evident in DNA from subclone SJ-150-B compared to SJ-150-A (about tenfold amplification) and subclone SJ-67-B compared to SJ-67-A (two- to fourfold amplification).

The heterodisperse pattern of fluorescence observed with the SJ-150-B subclone and monoclonal antibody MY7 (Fig 1A) suggested that human DNA sequences might be unstably amplified in these cells. We therefore attempted to sort gp150-negative cells from the SJ-150-B cell population based on reduced binding with the monoclonal antibody MY7. After three rounds of sorting, a revertant subpopulation (designated SJ-150-BR) that no longer exhibited MY7 binding was obtained. Despite the lack of binding with the gp150-specific antibody, the cells retained the transformed phenotype and continued to show as much binding of the v-*fms*-specific monoclonal antibody SM2.6.3 as that observed with the parental amplified SJ-150-B subclone.

Analysis of *Hind* III-digested DNA from subclones SJ-

150-B and SJ-150-BR after hybridization with probes prepared from both human repetitive DNA sequences and the FeSV-containing plasmid is shown in Fig 4. The characteristic human DNA restriction fragments representing the gp150 gene were considerably more difficult to detect in DNA from subclone SJ-150-BR, as compared with DNA from subclone SJ-150-B (lanes 1 and 2, Fig 4), indicating that gp150 coding sequences had been segregated. Hybridization with the FeSV plasmid probe also yielded a decreased signal intensity in DNA from SJ-150-BR cells as compared with SJ-150-B cells (lanes 3 and 4), although the hybridization intensity was less reduced than that observed with the human repetitive DNA probe. The same restriction fragments were observed in both subclones, reflecting their derivation from a single transformed cell. Therefore, at least some FeSV-containing plasmid sequences can segregate independently of gp150-coding sequences in these clones. Similar experiments were not attempted with subclone SJ-67-B, because the pattern of binding with the monoclonal antibody MY9 was uniformly amplified in these cells with no evidence of a fluorescence-negative subpopulation.

Cytogenetic evidence of gene amplification. Metaphases from transformed NIH-3T3 cell clones were examined for the cytogenetic hallmarks of gene amplification—DM chromatin bodies or ABRs.[11,12] Examination of cells from subclone SJ-150-B with amplified but unstable expression of gp150 showed that 88% of the metaphases contained DMs, at an average of 22 per metaphase (range, 3 to 50). A representative SJ-150-B metaphase spread illustrating multiple DMs per metaphase is shown in Fig 5A. To determine whether DMs were in fact related to overexpression of gp150, we examined metaphases from the SJ-150-BR revertant. These cells contained DMs in 43% of metaphases, with an average of nine DMs per metaphase. Metaphase spreads from subclone SJ-150-A were found to contain DMs at an even lower frequency (17% of metaphases), with an average of only one or two DMs per cell (range, 1 to 5).

The finding of low numbers of DMs in transfected cells lacking evidence of amplified human DNA sequences by Southern blotting led us to examine metaphases from the parental NIH-3T3 line. NIH-3T3 (clone 7) cells were found to contain a low frequency of DMs (10%), with an average of 1.6 per metaphase (range 1 to 3). The presence of distinctive

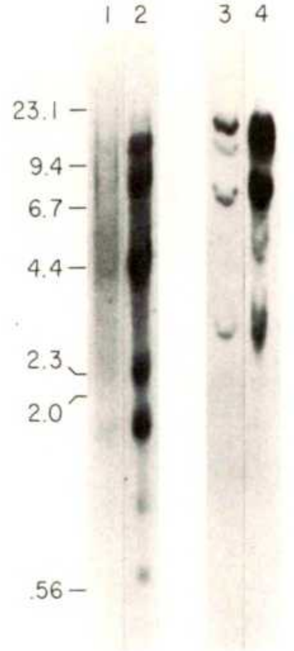

Fig 4. Southern blot analysis of human and FeSV plasmid-related DNA sequences in NIH-3T3 transformants (SJ-150-B) and in revertants (SJ-150-BR) derived from a single clone with unstable amplification of gp150 expression. *Hind* III digests of DNA (50 μg/lane) from subclones SJ-150-BR (lanes 1 and 3) or SJ-150-B (lanes 2 and 4) were hybridized with radiolabeled reiterated human DNA (lanes 1 and 2) or with a plasmid containing the complete FeSV provirus (lanes 3 and 4).

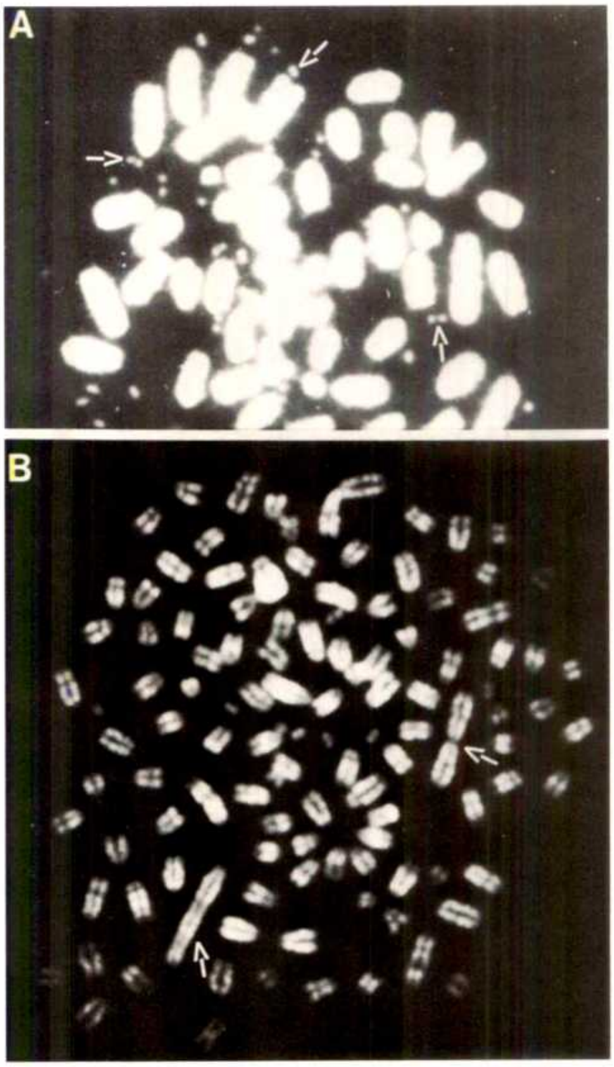

Fig 5. Quinacrine banding analysis of NIH-3T3 transformants SJ-150-B and SJ-67-B. (A): evidence of multiple copies of double minutes (arrows) from the SJ-150-B subclone; (B): demonstration of clonal marker chromosomes in SJ-67-B cells. Arrows indicate a long acrocentric marker chromosome displaying regions of heterochromatic DNA (bottom) as well as the presence of a single large metacentric marker chromosome (top).

marker chromosomes observed in the karyotypes from the transfected NIH-3T3 cells confirm the derivation of these DM-bearing cells from the clone 7 NIH-3T3 parent. Taken together, the results suggest that the expression of gp150 directly correlates with the number and percentage of cells displaying DMs, with high-expressing gp150 clones demonstrating a high number of DMs and low-expressing gp150 clones demonstrating a low number of DMs.

Metaphases from the SJ-67-B subclone displaying a stable pattern of amplified expression of p67 demonstrated extended chromosomal regions of heterochromatic DNA, which stained positively when analyzed with G-, Q-, and C-banding techniques (Figs 5B and 6). Regions of C-band-positive DNA are ordinarily associated with pericentromeric heterochromatin, which usually does not represent a site of active gene transcription. Although DMs were found in cells from subclone SJ-67-A at low frequency (similar to the NIH-3T3 parental cells), they were not detected in any cell from the SJ-67-B subclone.

Localization of human DNA sequences in transfected clones by in situ hybridization. To determine the localization of the human DNA sequences within the mouse genome, we used in situ hybridization.[36] The autoradiographic images of 50 mitotic cells were examined from the subclones SJ-67-B and SJ-150-B following in situ hybridization with ^{3}H-labeled human repetitive DNA.[16] Of the total chromosomal grains localized in SJ-67-B cells, 12% were observed on the near-terminal short arm of an unclassified metacentric marker chromosome (Fig 7). Significant chromosomal localization of the human sequences is consistent with the stable expression of the p67 polypeptide in this subclone. In contrast, in situ hybridization to the DM-bearing SJ-150-B subclone demonstrated a very different pattern of grain distribution, with no significant grain localization to any single mouse chromosome. The lack of a single cytologically recognizable site of chromosomal integration by in situ hybridization, coupled with the aforementioned correlation between the frequency of DMs in SJ-150-B cells and the expression of gp150 protein, make extrachromosomal DMs the likely site of amplified human sequences in this subclone. The size of the DMs in this cell line is essentially identical to the size of the autoradiographic grains following in situ hybridization, making direct localization of human sequences to DMs impossible.

DISCUSSION

DNA-mediated gene transfer into NIH-3T3 cells with the v-*fms* transforming gene as a dominant selectable marker permitted flow cytometric isolation of transformants with amplified expression of human myeloid differentiation antigens. A limited number of human DNA restriction frag-

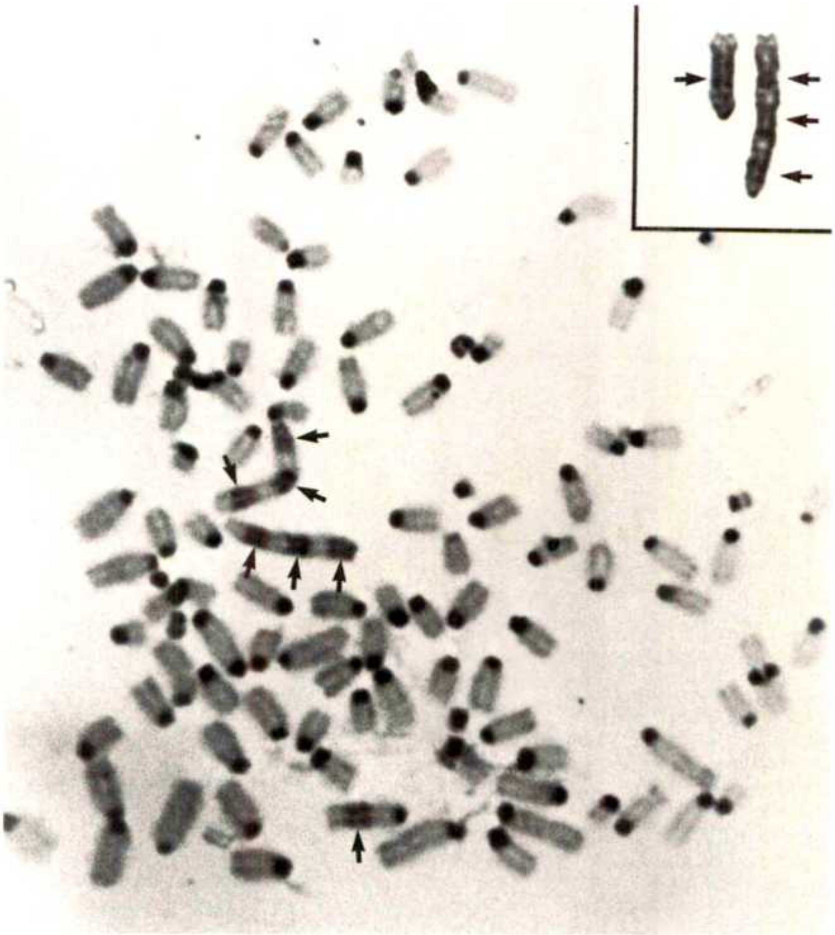

Fig 6. A typical metaphase spread from cloned NIH-3T3 transformants with amplified p67 expression (subclone SJ-67-B). Extended regions of heterochromatic DNA (arrows) were evident in C-banded metaphases. The large acrocentric marker chromosomes may have arisen from fusion of three of the abnormal 1 chromosomes (inset, from a G-banded metaphase).

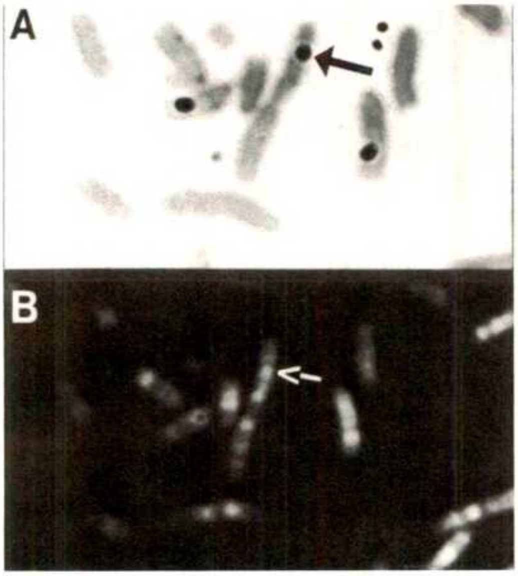

Fig 7. Partial metaphase demonstrating localization of human repetitive DNA utilizing in situ hybridization.[36] (A) Wright's staining demonstrating an autoradiographic grain on the short arm of the large metacentric marker chromosome. Twelve percent of all chromosomal grains localized to this band region. ments were amplified in cloned secondary or tertiary transformants that exhibited greatly increased expression of the cell membrane antigens, gp150 and p67, as compared with HL-60 donor cells. Transformants with stably amplified genes contained chromosomally integrated donor DNAs, whereas unstable gene amplification was associated with the presence of DMs. By selecting revertant clones, the amplified human DNA sequences in gp150-positive clones segregated with DMs, suggesting that copies of the gp150 gene were associated with these extrachromosomal elements. The failure to localize chromosomal sites of integration in gp150-positive cells was also consistent with the localization of transfected human DNA to DMs. Human DNA sequences did not map to extended heterochromatin regions of p67-positive cells, but rather to an unidentified marker chromosome seen in parental NIH-3T3 cells. Noncentromeric heterochromatic regions analogous to those found in the SJ-67-B subclone have been observed previously and were shown to be associated with increased metastatic potential in Rous sarcoma virus-transformed NIH-3T3 cells.[37] Thus, spontaneous amplification of unidentified mouse sequences in SJ-67-B cells may similarly reflect selection for increased growth potential after FeSV-mediated transformation. As has been found in other systems, amplification of the human DNA sequences in this subclone occurred without a cytogenetically evident ABR at the integration site. The formation of an ABR depends on the size of the amplified unit of DNA rather than on the degree of amplification of sequences encoding a single gene.[4]

Our results with the gp150-positive clones are analogous to those of Kavathas and Herzenberg,[14] who observed amplification of the gene encoding the human T cell membrane antigen Leu-2 (or T8) after co-transfection of human DNA with the cloned herpes simplex *tk* gene into *tk*-deficient mouse L cells. Such transformants provide ideal sources of template RNA for the generation of subtractive cDNA probes to identify genomic or cDNA clones of the transferred gene, as demonstrated for the Leu-2 antigen by these workers[15] and by Littman et al.[38]
